## Abstract

To what degree should societies allow inequality to be inherited? What role should estate taxation play in shaping the intergenerational transmission of welfare? We explore these questions by modeling altruistically-linked individuals who experience privately observed taste or productivity shocks. Our positive economy is identical to models with infinite-lived individuals where efficiency requires immiseration: inequality grows without bound and everyone's consumption converges to zero. However, under an intergenerational interpretation, previous work only characterizes a particular set of Pareto-efficient allocations: those that value only the initial generation's welfare. We study other efficient allocations where the social welfare criterion values future generations directly, placing a positive weight on their welfare so that the effective social discount rate is lower than the private one. For any such difference in social and private discounting we find that consumption exhibits mean-reversion and that a steady-state, cross-sectional distribution for consumption and welfare exists, where no one is trapped at misery. The optimal allocation can then be implemented by a combination of income and estate taxation. We find that the optimal estate tax is progressive: fortunate parents face higher average marginal tax rates on their bequests.

## 1 Introduction

Societies inevitably *choose* the inheritability of inequality. Some balance between equality of opportunity for newborns and incentives for altruistic parents is struck. We explore how this balancing act plays out to determine long-run inequality and draw some novel implications for optimal estate taxation.

---

\*For useful discussions and comments we thank Daron Acemoglu, Fernando Alvarez, George-Marios Angeletos, Abhijit Banerjee, Gary Becker, Olivier Blanchard, Ricardo Caballero, Dean Corbae, Bengt Holmstrom, Narayana Kocherlakota, Robert Lucas, Casey Mulligan, Roger Myerson, Chris Phelan, Gilles Saint-Paul, Nancy Stokey, Jean Tirole and seminar and conference participants at Chicago, Minnesota, MIT and the Texas Monetary Conference held at the University of Austin in honor of the late Scott Freeman. This work begun motivated by a seminar presentation of Chris Phelan at MIT in May 2004. We also have gained significant insight from a manuscript by Freeman and Sadler—we thank Dean Corbae for bringing it to our attention.

Existing normative models of inequality reach an extreme conclusion: inequality should be perfectly inheritable and rise steadily without bound, with everyone converging to absolute misery and a vanishing lucky fraction to bliss. This *immiseration* result is robust; requires very weak assumptions on preferences (Phelan, 1998); and obtains invariably in partial equilibrium (Green, 1987, Thomas and Worrall, 1990), in general equilibrium (Atkeson and Lucas, 1992), and across environments with moral-hazard regarding work effort or with private information regarding preferences or productivity (Aiyagari and Alvarez, 1995).<sup>1</sup>

We depart minimally from these contributions, adopting the same positive economic models, but a slightly different normative criterion. In a generational context, previous work with infinite-lived agents characterizes the instance where future generations are not considered *directly*, but only *indirectly* through the altruism of earlier ones. On the opposite side of the spectrum, Phelan (2005) proposes a social planner with equal weights on all future generations. Our interest here is in exploring a class of Pareto-efficient allocations that take into account the current population along with unborn future generations. We place a positive and vanishing Pareto weight on the expected utility of future generations, this leads effectively to a social discount rate that is lower than the private one.

This relatively small change produces a drastically different result: long-run inequality remains bounded, a steady-state, cross-sectional distribution exists for consumption and welfare, social mobility is possible and everyone avoids misery. Indeed, welfare typically remains above an endogenous lower bound that is strictly better than misery. This outcome holds however small the difference between social and private discounting, and regardless of whether the source of asymmetric information is privately observed preferences or productivity shocks.

We begin by modeling a positive economy that is identical to the taste-shock setup developed by Atkeson and Lucas (1992). Each generation is composed of a continuum of individuals who live for one period and are altruistic towards a single descendant. There is a constant aggregate endowment of the only consumption good in each period. Individuals are ex-ante identical, but experience idiosyncratic shocks to preferences that are only privately observed — thus ruling out first-best allocations. Feasible allocations must be incentive compatible and must satisfy the aggregate resource constraint in all periods.

When only the welfare of the first generation is considered, the planning problem is equivalent to that of an economy with infinite-lived individuals. Intuitively, immiseration then results from the desire to smooth the dynamic consumption path: rewards and punishments, required for incentives, are best delivered permanently. As a result, the consumption process inherits a random-walk component that leads cross-sectional inequality to grow endlessly without bound. Infinite spreading of the distribution is consistent with a constant aggregate endowment only if everyone's consump-

---

<sup>1</sup>Many find the immiseration result perplexing and some even find it morally questionable, but it is also inconvenient from a practical standpoint. Long-run steady-states often provide a natural benchmark to study dynamic economies, but such long-run analyses are not possible for private-information economies without a steady-state distribution with positive consumption. This has impaired the study of long-run implications of optimal taxation, so common in the Ramsey taxation literature.

tion eventually converges to zero. Note, that as a consequence, no steady-state, cross-sectional distribution with positive consumption exists.

Across generations, this arrangement requires a lock-step link between the welfare of parent and child. Of course, the perfect intergenerational transmission of welfare improves parental incentives — but at the expense of exposing newborns to the risk of their parent’s luck.

By contrast, it remains optimal to link the fortunes of parents and children in our model, but no longer in lock-step. Rewards and punishments are distributed over all future descendants, but in a front-loaded manner. This creates a mean-reverting tendency in consumption — instead of a random walk — that is strong enough to bound long-run inequality. The result is a steady-state cross-sectional distribution for consumption and welfare, with no fraction of the population stuck at misery.

We also study a repeated Mirrleesian version of our economy and derive implications for optimal estate taxation. In this model, individuals have identical preferences with regard to consumption and work effort, but are heterogenous in the productivity of their work effort. Information about productivity and work effort is private — only the resulting output is publicly observable. We show that the analysis from the taste-shock model carries over to this setup, virtually without change. In particular, a very similar Bellman equation characterizes the solution to the social planning problem: consumption exhibits mean-reversion and has a steady-state cross-sectional distribution. This outcome highlights the fact that our results do not require any particular asymmetry of information.

More importantly, the Mirrleesian model offers new insights into estate taxation. Feasible allocations can be implemented by combining income and estate taxes. Specifically, we find that a progressive estate tax, which imposes a higher average marginal tax rate on the bequests of fortunate parents, is optimal. This result reflects the mean-reversion of consumption: more fortunate dynasties, with relatively high levels of current consumption, must have a declining consumption path induced by higher estate tax rates that lower the net rates of return across generations.

Finally, an important methodological contribution of this paper is to reformulate the social planning problem recursively. In doing so, we extend ideas introduced by Spear and Srivastava (1987) to situations where private and social preferences differ. Indeed, we are able to reduce the dynamic program to a one-dimensional state variable, and our analysis and results heavily exploit the resulting Bellman equation.<sup>2</sup> Our dynamic program also offers an efficient and accurate computational strategy, as illustrated by an example in Section 4.

**Related Literature.** Our paper is most closely related to Phelan (2005), who considered a social planning problem with no discounting of the future. He shows that if a steady state for the planning problem exists then it must solve a static maximization problem, and that solutions to this problem have strictly positive inequality and social mobility. Our paper establishes the existence of a steady-state distribution for the planning problem for any difference in social and private discounting. Unlike the case with no discounting, there is no associated static planning problem for

---

<sup>2</sup>We also present a recursive formulation with a two-dimensional state-variable that has a very simple economic interpretation and is useful for developing an intuitive understanding of our results.

steady-state distributions, and as a result, the methods we develop here are very different.

In overlapping-generation models without altruistic links, all market equilibria that are Pareto efficient place positive direct weight on future generations. Bernheim (1989) was the first to point out that in the dynamic extension of these models with altruism, many Pareto efficient allocations are not attainable by the market. Kaplow (1995) argued that these Pareto efficient allocations are natural social objectives and that they can be implemented by market equilibria with estate taxation policy. The estate tax is negative — it is a subsidy — so as to internalize the externality of giving on future generations.

Our work contributes to a large literature on dynamic economies with asymmetric information. In addition to the work mentioned above, this includes recent research on dynamic optimal taxation (e.g., Golosov, Kocherlakota and Tsyvinski, 2003; Albanesi and Sleet, 2004; and Kocherlakota, 2004). This literature has been handicapped by the immiseration result and by the non-existence of a steady-state distribution with positive consumption, making it difficult to draw long-run conclusions for optimal taxation. Our results provide an encouraging way to overcome this problem.

Our work is also indirectly related to a paper by Sleet and Yeltekin (2004), who study an Atkeson-Lucas environment with a utilitarian planner, who lacks commitment and cares only for the current generation. In this environment, as in Phelan's, it is a foregone conclusion that immiseration will not hold, so the interesting question is how to solve for the best subgame-perfect equilibria. Sleet and Yeltekin derive first-order conditions from a Lagrangian and use these to numerically simulate the solution. Interestingly, it turns out that the best allocation in their no-commitment environment is asymptotically equivalent to the optimal one with commitment but featuring a more patient welfare criterion. Thus, our analysis and results provide an indirect, but effective way of characterizing the no-commitment problem and of formally establishing that a steady-state distribution with no one at misery exists.

The rest of the paper is organized as follows. Section 2 introduces the economic environment and sets up the social planning problem. In Section 3, we develop a recursive version of the planning problem and draw its connection to our original formulation. The resulting Bellman equation is then put to use in Section 4 to characterize the solution to the social planning problem. Here we derive our main results on mean-reversion and on the existence of a steady-state distribution for consumption. We discuss these results in Section 5 and develop intuition for them by studying some related problems and reformulations. In Section 6, we turn to the canonical optimal-taxation setup with productivity shocks and focus on its implications for estate taxes. Section 7 offers some conclusions from the analysis. All proofs omitted in the main text are contained in the Appendix.

## 2 A Social Insurance Problem

The backbone of our model requires a tradeoff between insurance and incentives. This tradeoff can be due to private information regarding either productivity or preferences. For purposes of comparison, we first adopt the Atkeson-Lucas taste-shock specification. In Section 6, we adapt our

arguments to a repeated Mirrleesian model with privately observed productivity shocks. Similar arguments could be applied to moral-hazard situations with unobservable effort choices.

Our positive economy is identical to that of Atkeson-Lucas — the differences are only normative. An infinite-lived agent can be interpreted as a dynasty of individuals who have finite lives but are altruistically linked. Under this interpretation, Atkeson-Lucas and others focus on a particular set of efficient allocations: those that only directly consider the welfare of the initial generation.<sup>3</sup> In contrast, our interest here lies with efficient allocations that directly weigh the welfare of all future generations. This approach is asymptotically equivalent to postulating preferences for an infinitely-lived social planner who is more patient than individuals.

**Demography, Preferences and Technology.** At any point in time, our economy is populated by a continuum of individuals who have identical preferences, live for one period, and are replaced by a single descendant in the next. Parents born in period  $t$  are altruistic towards their only child and their utility  $v_t$  satisfies

$$v_t = \mathbb{E}_{t-1} [\theta_t u(c_t) + \beta v_{t+1}],$$

where  $c_t \geq 0$  is the parent's own consumption and  $\beta \in (0, 1)$  is the altruistic weight placed on the descendant's utility  $v_{t+1}$ . We assume that the utility function  $u : \mathbb{R}_+ \rightarrow \mathbb{R}$  is continuous, concave, and continuously differentiable for positive consumption levels, with the Inada conditions  $u'(0) = \infty$  and  $u'(\infty) = 0$ . The extremes  $\underline{u} \equiv u(0)$  and  $\bar{u} \equiv u(\infty)$  may or may not be finite. We let  $c(u)$  denote the inverse of the utility function  $c \equiv u^{-1}$ , or cost function. The taste shock  $\theta \in \Theta$  is distributed identically and independently across individuals and time. For simplicity, we assume  $\Theta$  is finite and adopt the normalization that  $\mathbb{E}[\theta] = 1$ .

This specification of altruism is consistent with individuals having a preference over the entire future consumption of their dynasty given by

$$v_t = \sum_{s=0}^{\infty} \beta^s \mathbb{E}_{t-1} [\theta_{t+s} u(c_{t+s})]. \quad (1)$$

In each period, a resource constraint limits aggregate consumption to be no greater than some constant aggregate endowment  $e > 0$ . These specifications of individual preferences and technology are precisely those adopted by Atkeson-Lucas.

**Social Welfare.** We depart from Atkeson-Lucas by assuming that the social welfare criterion can be represented by preferences given by the utility function

$$\sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u(c_t)], \quad (2)$$

with  $\hat{\beta} > \beta$ . Thus, social preferences are identical to the individual preferences given by (1), except

---

<sup>3</sup>The final paragraph in Atkeson-Lucas's paper discusses the possible importance of relaxing this assumption. However, the approach taken in the literature has been to impose an exogenous lower bound on ex-post lifetime utility, as in Atkeson and Lucas (1993) and Albanesi and Sleet (2004).

for the discount factor.

This setup puts weight on the welfare of future generations directly. Future generations are already indirectly valued through the altruism of the current generation. If, in addition, they are also *directly* included in the welfare function the social discount factor must be higher than  $\beta$ . To see this, consider the utilitarian welfare criterion

$$\sum_{t=0}^{\infty} \alpha^t \mathbb{E}_{-1} v_t = \sum_{t=0}^{\infty} \delta_t \mathbb{E}_{-1} [\theta_t u(c_t)], \quad (3)$$

where  $\delta_t \equiv \beta^t + \beta^{t-1}\alpha + \cdots + \beta\alpha^{t-1} + \alpha^t$ . Then the discount factor satisfies

$$\frac{\delta_{t+1}}{\delta_t} = \beta + \frac{\alpha^{t+1}}{\delta_t} > \beta$$

and social preferences are more patient. In the limit  $\delta_{t+1}/\delta_t \rightarrow \max\langle\beta, \alpha\rangle$ , so the welfare criterion (3) approaches (2) with  $\hat{\beta} = \max\langle\beta, \alpha\rangle$ .<sup>4</sup><sup>5</sup>

Atkeson-Lucas' analysis applies to the case with  $\beta = \hat{\beta}$ , so we focus on the case where enough weight is placed on future generations to ensure that the long-run social discount factor remains strictly higher than the private one,  $\hat{\beta} > \beta$ . Although we adopt the preference in (2) directly for the rest of the paper, we also briefly show how our analysis can be easily adapted to work with the welfare criterion (3). These two specifications are slightly different for any finite horizon but are identical for the long-run, which is our primary concern.

**Information and Incentives.** Taste shock realizations are privately observed by individuals and their descendants. The revelation principle then allows us to restrict our attention to mechanisms that rely on truthful reports of these shocks. Thus, each dynasty faces a sequence of consumption functions  $\{c_t\}$ , where  $c_t(\theta^t)$  represents an individual's consumption after reporting the history  $\theta^t \equiv (\theta_0, \theta_1, \dots, \theta_t)$ . A dynasty's reporting strategy  $\sigma \equiv \{\sigma_t\}$  is a sequence of functions  $\sigma_t : \Theta^{t+1} \rightarrow \Theta$  that maps histories of shocks  $\theta^t$  into a current report  $\hat{\theta}_t$ . Any strategy  $\sigma$  induces a history of reports  $\sigma^t : \Theta^t \rightarrow \Theta^t$ . We use  $\sigma^*$  to denote the truth-telling strategy with  $\sigma_t^*(\theta^t) = \theta_t$  for all  $\theta^t \in \Theta^t$ .

Given an allocation  $\{c_t\}$ , the utility obtained from any reporting strategy  $\sigma$  is

$$U(\{c_t\}, \sigma; \beta) \equiv \sum_{t=0}^{\infty} \sum_{\theta^t \in \Theta^{t+1}} \beta^t \theta_t u(c_t(\sigma^t(\theta^t))) \Pr(\theta^t).$$

---

<sup>4</sup>Caplin and Leahy (2005) argue that a similar logic applies to intra-personal discounting within a lifetime. This leads to a social discount factor that is greater than the private one not only across generations, but within generations as well.

<sup>5</sup>One can also adopt the more general welfare criterion  $\mathbb{E}_{-1} \sum_{t=0}^{\infty} \alpha_t v_t$  for some sequence of positive Pareto weights  $\{\alpha_t\}$ , where the weight  $\alpha_t$  can be interpreted as the probability of being born into generation  $t$  for "souls behind the veil of ignorance." In particular, the sequence  $\alpha_0 = (1 - \hat{\beta})/(1 - \beta)$  and  $\alpha_t = \alpha_0 \hat{\beta}^t$  for  $t \geq 1$  delivers  $\delta_{t+1}/\delta_t = \hat{\beta}$  for all  $t = 0, 1, \dots$

An allocation  $\{c_t\}$  is *incentive compatible* if truth-telling is optimal:

$$U(\{c_t\}, \sigma^*; \beta) \geq U(\{c_t\}, \sigma; \beta). \quad (4)$$

**Social Planning Problem.** Following Atkeson-Lucas, we identify each dynasty with a number  $v$ , which we interpret as its initial entitlement to expected, discounted utility,  $v_0 = v$ . We assume that all dynasties with the same entitlement  $v$  receive the same treatment. We then let  $\psi$  denote a distribution of utilities  $v$  across the population of dynasties:  $\psi(A)$  is the fraction of dynasties who will receive expected discounted utility in the set  $A \subset \mathbb{R}$ .

An allocation is a sequence of functions  $\{c_t^v\}$  for each  $v$ , where  $c_t^v(\theta^t)$  represents the consumption that a dynasty with initial entitlement  $v$  gets at date  $t$  after reporting the sequence of shocks  $\theta^t$ . For any given initial distribution of entitlements  $\psi$  and resources  $e$ , we say that an allocation  $\{c_t^v\}$  is *feasible* if: (i) it is incentive compatible for all dynasties; (ii) it delivers expected utility of at least  $v$  to all initial dynasties entitled to  $v$ ; and (iii) average consumption in the population does not exceed the fixed endowment  $e$  in all periods.

A social optimum maximizes the average social welfare function, weighed by  $\psi$ , over all feasible allocations. That is, the *social planning problem* given an initial distribution of entitlements  $\psi$  is to maximize

$$\int U(\{c_t^v\}, \sigma^*, \hat{\beta}) d\psi(v)$$

subject to  $v = U(\{c_t^v\}, \sigma^*; \beta) \geq U(\{c_t^v\}, \sigma; \beta)$  for all  $v$ , and

$$\int \sum_{\theta^t} c_t^v(\theta^t) \Pr(\theta^t) d\psi(v) \leq e \quad t = 0, 1, \dots \quad (5)$$

**Steady States.** Our focus is on distributions of utility entitlements  $\psi$  such that the solution to the planning problem features, in each period, a cross-sectional distribution of continuation utilities  $v_t$  that is also distributed according to  $\psi$ . We also require the cross-sectional distribution of consumption to replicate itself over time. We term any initial distribution of entitlements with these properties a *steady state* and denote them by  $\psi^*$ . As we shall demonstrate below, continuation utility constitutes a state variable that follows a Markov process, and steady states are then invariant distributions of this process.

Note that in the Atkeson-Lucas case, with  $\beta = \hat{\beta}$ , the non-existence of a steady state with positive consumption is a consequence of the immiseration result. Starting from any initial distribution of entitlements the sequence of distributions converges weakly to the distribution having full mass at misery and zero consumption for everyone. This distribution constitutes a trivial steady state, which does not exhaust the endowment and is Pareto dominated by an allocations that improves everyone's welfare and the social welfare criterion. In contrast, in our model we seek non-trivial steady states that exhaust the aggregate endowment in all periods.

### 3 A Bellman Equation

In this section we study a relaxed version of the social planning problem. This has two advantages: First, because the relaxed problem can be solved by studying a set of subproblems — one for each dynasty with entitlement  $v$  — we avoid the need to keep track of the entire population. Second, each of these subproblems admits a simple recursive formulation, which can be characterized quite sharply.

Consider a *relaxed planning problem* where the sequence of resource constraints (5) is replaced by the single intertemporal condition

$$\int \sum_{t=0}^{\infty} Q_t \sum_{\theta^t} c_t^v(\theta^t) \Pr(\theta^t) d\psi(v) \leq e \sum_{t=0}^{\infty} Q_t, \quad (6)$$

for some positive sequence  $\{Q_t\}$  with  $\sum_{t=0}^{\infty} Q_t < \infty$ . One can interpret this problem as representing a small open economy facing intertemporal prices  $\{Q_t\}$ . The relaxed and original versions of the planning problem are related in that any solution to the former which happens to satisfy the resource constraints in (5) must also be a solution to the latter. A Lagrangian argument establishes the converse: there must exist some positive sequence  $\{Q_t\}$  such that the solution to the original planning problem also solves the relaxed problem. Most importantly, any steady-state solution to the relaxed problem is a steady-state solution to the original one.

Our focus on steady states leads naturally to  $Q_t = q^t$  for some  $q > 0$ . Indeed, steady states are only compatible with  $q = \hat{\beta}$ , so we adopt this value for the relaxed problem from this point forward.<sup>6</sup> Attaching a multiplier  $\hat{\lambda} > 0$  to the intertemporal resource constraint (6), we can form the Lagrangian  $L \equiv \int L^v d\psi(v)$  where

$$L^v \equiv \sum_{t=0}^{\infty} \sum_{\theta^t} \hat{\beta}^t (u(c_t^v) - \hat{\lambda} c_t^v(\theta^t)) \Pr(\theta^t)$$

and study the optimization of  $L$  subject to  $v = U(\{c_t^v\}, \sigma^*; \beta) \geq U(\{c_t^v\}, \sigma; \beta)$  for all  $v$ . This is equivalent to the pointwise optimization, for each  $v$ , of the subproblem  $k(v) \equiv \sup L^v$  subject to  $v = U(\{c_t^v\}, \sigma^*; \beta) \geq U(\{c_t^v\}, \sigma; \beta)$ . Where there is no risk of confusion, we henceforth drop the superscript  $v$  when denoting allocations  $\{c_t^v\}$ .

Our first result characterizes the value function and shows that it satisfies the Bellman equation

$$k(v) = \max_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))] \quad (7)$$

subject to

$$v = \mathbb{E}[\theta u(\theta) + \beta w(\theta)] \quad (8)$$

---

<sup>6</sup>A simple variational argument can be used to show that  $Q_{t+1}/Q_t = \hat{\beta}$  for any relaxed problem at an invariant distribution with a finite average value for  $c'(u_t)$ .

$$\theta u(\theta) + \beta w(\theta) \geq \theta u(\theta') + \beta w(\theta') \quad (9)$$

for all  $\theta, \theta' \in \Theta$ .<sup>7</sup>

**Theorem 1** *The value function  $k(v)$  is continuous, concave, and satisfies the Bellman equation (7)-(9).*

The recursive formulation imposes a promise-keeping constraint (8) and an incentive constraint (9). Intuitively, the latter rules out one-shot deviations from truth-telling, guaranteeing that telling the truth today is optimal if the truth is told in future periods. This is necessary to satisfy the full incentive-compatibility condition (4). The rest is implicitly taken care of in (7) by evaluating the value function at the continuation utility: for any given continuation value  $w(\theta)$ , envision the planner in the next period solving the remaining sequence problem by selecting an entire allocation that is incentive compatible from then on. Then  $k(w(\theta))$  represents the value to the planner of this continuation allocation. Taken together, a pair  $u(\theta)$  and  $w(\theta)$  that satisfies (8)-(9) pasted with the corresponding continuation allocations for each  $w(\theta)$ , yields an allocation that satisfies the full incentive-compatibility (4). The objective function in (7) then represents the value to the planner of this allocation.

Among other things, Theorem 1 shows that the maximum in the Bellman equation (7) is attained. We let the policy functions  $g^u(\theta, v)$  and  $g^w(\theta, v)$  denote the unique solutions for  $u$  and  $w$ , respectively. For any initial utility entitlement  $v_0$ , an allocation  $\{u_t\}$  can then be generated from the policy functions  $(g^u, g^w)$  by setting  $u_0(\theta_0) = g^u(\theta_0, v_0)$  and defining  $u_t(\theta^t)$  and  $v_{t+1}(\theta^t)$  recursively for  $t \geq 1$  using  $u_t(\theta^t) = g^u(\theta_t, v_t(\theta^{t-1}))$  and  $v_{t+1}(\theta^t) = g^w(\theta_t, v_t(\theta^{t-1}))$ .

Our next result elucidates the connection between allocations generated from the policy functions in this way and solutions to the planning problem.

**Theorem 2** *(a) An allocation  $\{u_t\}$  is optimal for the relaxed problem, given  $v_0$ , if and only if it is generated by the policy functions  $(g^u, g^w)$  starting at  $v_0$ , is incentive compatible, and delivers a lifetime utility of  $v_0$ ; (b) an allocation  $\{u_t\}$  generated by the policy functions  $(g^u, g^w)$ , starting at  $v_0$ , has  $\lim_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^{t-1}) = 0$  and delivers utility  $v_0$ ; (c) an allocation  $\{u_t, v_t\}$  generated by the policy functions  $(g^u, g^w)$ , starting from  $v_0$ , is incentive compatible if*

$$\limsup_{t \rightarrow \infty} \mathbb{E}_{-1} \beta^t v_t(\sigma^{t-1}(\theta^{t-1})) \geq 0$$

for all reporting strategies  $\sigma$ .

Part (a) of Theorem 2 implies that either the solution to the relaxed planning problem is generated by the policy functions of the Bellman equation, or there is no solution at all. Parts (b) and (c) of the theorem show that the first case is guaranteed if we can verify the limit condition in

---

<sup>7</sup>We study a Bellman equation that also characterizes the problem for  $q \neq \hat{\beta}$  in Section 5.

part (b). The latter is automatically satisfied for all utility functions that are bounded below and we will see that it can be verified in other cases of interest.<sup>8</sup>

We close this section with a detour and state the Bellman for the relaxed planning problem associated with maximizing the welfare criterion (3). Define  $\tilde{k}(v) \equiv \sup \sum_{t=0}^{\infty} \alpha^t \mathbb{E}_{-1}[v_t - \hat{\lambda} c_t^v]$  subject to  $v = U(\{c_t^v\}, \sigma^*; \beta) \geq U(\{c_t^v\}, \sigma; \beta)$ . Then very similar arguments imply that the value function  $\tilde{k}(v)$  satisfies the Bellman equation

$$\tilde{k}(v) = \max_{u,w} \mathbb{E}[v - \hat{\lambda} c(u(\theta)) + \alpha \tilde{k}(w(\theta))]$$

subject to (8) and (9). Because this Bellman equation is almost identical to the one in (7), the analysis and results that follow can easily be adapted to this case.

## 4 Optimal Inequality

In this section we exploit the connection between the Bellman equation and the planning problem. We characterize the solution and derive a key equation that illustrates mean-reverting forces in the dynamics of consumption. The main result of the section is to establish that these forces are strong enough to imply the existence of an invariant distribution with no misery. Finally, we provide sufficient conditions that verify the requirements of Theorem 2, and ensure that a solution to the planning problem exists.

### Mean Reversion

We are now in a position to study the Bellman equation's optimization problem. To begin, we justify the use of first-order conditions with the following lemma:

**Lemma 1** *The value function  $k(v)$  is strictly concave and differentiable on the interior of its domain, with  $\lim_{v \rightarrow \bar{v}} k'(v) = -\infty$ . If utility is unbounded below, then  $\lim_{v \rightarrow \underline{v}} k'(v) = 1$ . Otherwise  $\lim_{v \rightarrow \underline{v}} k'(v) = \infty$ .*

Let  $\lambda = k'(v)$  be the multiplier on the left-hand side of the promise-keeping constraint (8) and let  $\mu(\theta, \theta')$  be the multipliers on the incentive constraints (9). The first-order condition for  $u(\theta)$  is

$$(1 - \hat{\lambda} c'(u(\theta))) p(\theta) - \theta \lambda p(\theta) + \sum_{\theta'} \theta \mu(\theta, \theta') - \sum_{\theta'} \theta' \mu(\theta, \theta') \leq 0,$$

---

<sup>8</sup>Theorem 2 involves various applications of versions of the Principle of Optimality. For example, given policy functions  $(g^u, g^w)$  and an initial value  $v_0$ , the individual dynasty faces a recursive dynamic programming problem with state variable  $v$ . Conditions (8) and (9) then amount to guessing and verifying a solution to the Bellman equation of the agent's problem. In particular, that the value function that solves the Bellman equation, with truth telling, is the identity function. However, one needs to verify that this value function indeed represents the true value from the maximization of the dynasty's sequential problem. This verification is accomplished by part (c) of Theorem 2.

with equality if  $u(\theta)$  is interior. The solution for  $w(\theta)$  must be interior, given the Inada conditions for  $k(v)$  derived in Lemma 1, and must satisfy the first-order condition

$$\hat{\beta}k'(w(\theta))p(\theta) - \beta\lambda p(\theta) + \beta \sum_{\theta'} \mu(\theta, \theta') - \beta \sum_{\theta'} \mu(\theta, \theta') = 0.$$

Using the envelope condition  $k'(v) = \lambda$  and adding up across  $\theta$ , this becomes

$$\sum_{\theta \in \Theta} k'(w(\theta))p(\theta) = \frac{\beta}{\hat{\beta}}k'(v).$$

This key equation can be represented in sequential notation as

$$\mathbb{E}_{t-1}[k'(v_{t+1}(\theta^t))] = \frac{\beta}{\hat{\beta}}k'(v_t(\theta^{t-1})). \quad (10)$$

where  $\{v_t\}$  is generated by the policy function  $g^w$ . Thus,  $\{k'(v_t)\}$  is a Conditional Linear Auto Regressive (hereafter: CLAR) Markov process. Note that we can translate anything about the process  $\{k'(v_t)\}$  into implications for the process  $\{v_t\}$ , since the derivative  $k'(v)$  is continuous and strictly decreasing. Likewise, using the policy function  $g^u(\theta, v)$ , conclusions about the process  $\{v_t\}$  provide information about the process for consumption.

The conditional expectation in (10) illustrates that  $\beta/\hat{\beta} < 1$  creates a force for mean reversion for the process  $\{k'(v_t)\}$  toward zero. Lemma 1 implies that the value function  $k(v)$  has an interior maximum, so reversion occurs towards an interior utility level — away from misery. This feature is key to our results on the existence of invariant distributions. By contrast, in the Atkeson-Lucas model with  $\beta = \hat{\beta}$ , a CLAR equation similar to (10) also holds, but the relevant value function in this case is monotone.

To see this we write the Bellman equation for the relaxed problem in the Atkeson-Lucas case and derive its CLAR Euler equation. Even though no steady state exists in this model, if we assume a constant relative risk aversion utility function, then the relaxed problem does characterize the social planning problem for an appropriately chosen value of the price  $q_{AL}$ . The associated Bellman equation is

$$K_{AL}(v) = \min_{u,w} \mathbb{E}[c(u(\theta)) + q_{AL}K_{AL}(w(\theta))]$$

subject to (8) and (9). Crucially, here the value function  $K_{AL}(v)$  is strictly increasing, so that  $K'_{AL}(v) \geq 0$ . The envelope and first-order conditions yield the CLAR Euler equation

$$\sum_{\theta} K'_{AL}(w(\theta))p(\theta) = \frac{\beta}{q_{AL}}K'_{AL}(v),$$

similar to condition (10) when  $q_{AL} \geq \beta$ .<sup>9</sup> However, the critical difference is that here  $\{K'_{AL}(v_t)\}$  is a non-negative process, which implies by the Martingale Convergence Theorem that it must converge almost surely (a.s.) to some finite value. Since incentives must be provided using continuation utilities  $g^w(\bar{\theta}, v) \neq g^w(\underline{\theta}, v)$ , this rules out anything other than  $K'_{AL}(v_t) \rightarrow 0$  a.s. Immiseration then follows,  $v_t \rightarrow \underline{v}$  and  $c_t \rightarrow 0$  a.s. This highlights the technical importance of our value function's non-monotonicity, which in turn hinges on the lower social discounting  $\hat{\beta} > \beta$ .

Economically, the mean-reversion equation implies a form of social mobility. That is, descendants of individuals with current welfare above  $v$  will eventually fall below  $v^*$ , and vice versa. The resulting rise and fall of families illustrates a strong intergenerational mobility in the model.

Our next result pushes the characterization of reversion past the average behavior of the  $\{k'_t\}$  process by deriving bounds for its evolution. These bounds are critical for guaranteeing the existence of an invariant distribution with no mass at misery. We summarize the previous CLAR equation and state the next result in the following proposition:

**Proposition 1** *The policy function satisfies*

$$\sum_{\theta \in \Theta} k'(g^w(\theta, v)) p(\theta) = \frac{\beta}{\hat{\beta}} k'(v).$$

Define the constants

$$\begin{aligned}\bar{\gamma} &\equiv (\beta/\hat{\beta}) \max_{1 \leq n \leq N} ((1 + \theta_n - \mathbb{E}(\theta \leq \theta_n))/\theta_n), \\ \underline{\gamma} &\equiv (\beta/\hat{\beta}) \min_{2 \leq n \leq N} (1 + \theta_{n-1} - \mathbb{E}[\theta \mid \theta \geq \theta_n]/\theta_{n-1}).\end{aligned}$$

Then (a) if utility is unbounded below,

$$\underline{\gamma}(1 - k'(v)) + \left(1 - \frac{\beta}{\hat{\beta}}\right) \leq 1 - k'(g^w(\theta, v)) \leq \bar{\gamma}(1 - k'(v)) + \left(1 - \frac{\beta}{\hat{\beta}}\right) \quad (11)$$

and (b) if utility is bounded below with  $u(0) = 0$ , for values of  $v$  such that  $k'(v) > 1$ , we have

$$\begin{aligned}u(\theta) &= 0 \\ w(\theta) &= \beta^{-1}v > v \\ k'(w(\theta)) &= (\hat{\beta}/\beta)k'(v)\end{aligned}$$

for all  $\theta \in \Theta$ . For values of  $v$  such that  $k'(v) \leq 1$ , the lower bound in (11) holds; the upper bound in (11) holds for sufficiently high  $v$ .

---

<sup>9</sup>With logarithmic utility the partial equilibrium solution with  $q_{AL} = \beta$  features constant average consumption. Thus, it is also a solution to the problem that imposes an aggregate resource constraint in every period. With the constant relative risk aversion utility function  $u(c) = c^{1-\sigma}/(1-\sigma)$  there is a value of  $q_{AL}$ , for each value of  $\sigma$ , that has the same effect. Indeed, for  $\sigma \leq 1$  the appropriate  $q_{AL}$  satisfies  $q_{AL} \geq \beta$ .

Proposition 1 illustrates a powerful tendency away from misery. For example, with utility unbounded below, continuation utility  $g^w(\theta, v)$  remains bounded even as  $v \rightarrow -\infty$ . Thus, no matter how much a parent is supposed to be punished, his child is always somewhat spared.

## Main Result: Existence of an Invariant Distribution with No Misery

We now state the main result of this section: if a solution to the relaxed planning problem exists, then it admits an invariant distribution with no misery. The proof of this result relies on the conditional-expectation equation (10) and the bounds in Proposition 1. Thus, it makes use of both mean-reversion properties discussed in the previous subsection.<sup>10</sup>

**Proposition 2** *The existence of an invariant distribution  $\psi^*$  with no mass at misery,  $\psi^*(\{\underline{v}\}) = 0$ , for the Markov process  $\{v_t\}$  implied by  $g^w$  is guaranteed if either: utility is unbounded below, utility is bounded above, or  $\hat{\gamma} < 1$ .*

Proposition 2, when combined with part (a) of Theorem 2, leaves open only two possibilities: (i) the relaxed problem admits a steady-state invariant distribution with no misery; or (ii) no solution exists. This situation contrasts strongly with the Atkeson-Lucas case, with  $\beta = \hat{\beta}$ , where a solution exists but does not admit a steady state, and everyone ends up at misery. Towards the end of this section we show that a solution to the planning problem can be guaranteed so that case (i) holds.

Our Bellman equation also provides an efficient method for explicitly solving the planning problem. We illustrate this with two examples, one analytical and another numerical.

**Example 1.** Suppose utility is CRRA with  $\sigma = 1/2$ , so that  $u(c) = 4c^{1/2}$  for  $c \geq 0$  and  $c(u) = u^2/2$  for  $u \geq 0$ . Atkeson-Lucas cover this case for  $\beta = \hat{\beta}$  and show that the optimum involves consumption inequality growing without bound, leading to immiseration.

Consider the relaxed problem where we ignore the non-negativity constraints on  $u$  and  $w$ ,

$$k(v) = \max_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda}u(\theta)^2/2 + \hat{\beta}k(w(\theta))],$$

subject to (8) and (9). This is a linear quadratic dynamic programming problem, so the solution is a quadratic value function with linear policy functions in  $v$ :

$$\begin{aligned} g^u(\theta, v) &= \gamma_1^u(\theta)v + \gamma_0^u(\theta) \\ g^w(\theta, v) &= \gamma_1^w(\theta)v + \gamma_0^w(\theta) \end{aligned}$$

For taste shocks with sufficiently small amplitude we can guarantee, by continuity with the deterministic case  $\underline{\theta} = \bar{\theta}$ , that  $\gamma^u(\theta) < 1$  and  $\gamma^w(\bar{\theta}) > 0$ , implying a unique bounded ergodic set for utility  $[v_L, v_H]$  with  $v_L > 0$ . Moreover,  $g^u(\theta, v) > 0$  for  $v \in [v_L, v_H]$ . Hence, since the planning problem is

---

<sup>10</sup>When utility is bounded below, we either require that utility be bounded above, or that  $\hat{\gamma} < 1$  — which is ensured for a small dispersion of the shocks — as a simple way of ensuring that the ergodic set is bounded away from misery. It seems very plausible, however, that these conditions could be dispensed with.

Figure 1: Policy functions  $g^w(\theta, v)$

Figure 2: Policy function  $g^c(\theta, w)$

convex and utility turns out to be strictly positive at the steady state, this solution does solves the original problem with non-negativity constraints on  $u$ .

**Example 2.** To illustrate the numerical value of our recursive formulation, we compute the solution for the logarithmic case with  $\beta = 0.9$ ,  $\hat{\beta} = 0.975$ ,  $e = (\lambda)^{-1} = 0.6$ ,  $\theta_h = 1.2$ ,  $\theta_l = 0.75$  and  $p = 0.5$ . We iterated on the Bellman equation for  $k(v)$  until convergence.<sup>11</sup>

Figure 1 plots the policy function for continuation utility in consumption-equivalent units,  $c(v(1 - \beta))$  against  $c(g^w(\theta, v)(1 - \beta))$ , while Figure 2 does the same for the policy function for consumption,  $c(v(1 - \beta))$  against  $g^c(\theta, v)$ . Both policy functions are monotonic and smooth. Figure 1 reveals a unique, bounded ergodic set for  $v$ . Note that both policy functions become nearly flat for low values of  $v$ . This illustrates the result, discussed immediately after Proposition 1, that utility is kept above some endogenous bound.

Figure 3 displays the steady-state, cross-sectional distribution of dynamic utility measured in consumption-equivalent units,  $c(v(1 - \beta))$  implied by the solution to the planning problem.<sup>12</sup> The

<sup>11</sup>The details of this numerical exercise where as follows: we solved for  $u(\theta)$  as a function of  $w(\theta)$  using the incentive and promise-keeping constraints. We then maximized over  $w(\theta)$ . We employed a grid for  $v$  defined in terms of equally spaced consumption-equivalent units  $c((1 - \beta)v) = \{0.01, \dots, 2\}$ . Results with a grid size of 100 and 300 were similar; we report the latter. We used Matlab's splines package to interpolate the value function and used `fmincon.m` as our optimization routine over  $w(\theta)$ . Our iterations were initialized with the value function corresponding to the feasible plan that features constant consumption:

$$k_0(v) = \frac{v(1 - \beta) - \hat{\lambda}c(v(1 - \beta))}{1 - \hat{\beta}}$$

We stopped the iterations when  $\|k_n(v) - k_{n-1}(v)\| < 10^{-10}$  and verified that the policy functions had also converged. Note that  $g^w(\theta, v)$  is well within the interior of  $[.01, 2]$ , so that the arbitrary upper and lower bounds from our grid choice were not found to be binding.

<sup>12</sup>The invariant distribution was approximated by generated a Monte Carlo simulation for the dynamics of the  $v_t$  process generated by  $g^w$ , with an arbitrary initial value of  $v_0$ . Since this process converges to a unique invariant distribution  $\psi$ , starting from any initial value of  $v_0$ , the frequencies in a long time-series sample approach the frequencies of  $\psi$ . To create the figure we used Matlab's Wavelet Toolbox to approximate the density from the simulated Monte-Carlo sample.

Figure 3: Steady-State Distributions of Dynamic Utility

long-run distribution has a smooth bell-curve shape — a feature that must be due to the smooth, mean-reverting dynamics of the model, since it cannot be a direct consequence of our two-point distribution of taste shocks. The figure also shows the invariant distributions for various values of  $\hat{\beta}$ . The degree of inequality appears to decrease with higher values of  $\hat{\beta}$ . This outcome is suggested intuitively by the coefficient on the CLAR equation (10) and the discussion in Section 5 on features of the impulse response to shocks. These simulations also support the natural conjecture that as we approach the Atkeson-Lucas case,  $\hat{\beta} \rightarrow \beta$ , the resulting sequence of invariant distributions blows up, since no steady state with positive consumption exists when  $\hat{\beta} = \beta$ .

We now turn briefly to issues of uniqueness and stability for the invariant distribution guaranteed by Proposition 2. This question is of economic interest because it represents an even stronger notion of social mobility than that implied by the mean-reversion condition (10) discussed in the previous subsection. That is, if convergence toward the distribution  $\psi^*$  occurs starting from any initial utility level  $v_0$ , then the fortunes of distant descendants — the distribution of their welfare — is independent of the individual's present condition. At the optimum, the past always exerts some influence on the present, but its influence is bounded and dies out over time, so that the advantages or disadvantages of distant ancestors are eventually wiped out.

Indeed, under some conditions we can guarantee that the social optimum in our model does display this strong notion of social mobility. To see this, suppose the ergodic set for the  $\{k'_t\}$  process is compact. This is guaranteed, for example, by applying Proposition 1 when  $\bar{\gamma} < 1$ . Then, if the policy function  $g^w(\theta, v)$  is monotone in  $v$ , the invariant distribution  $\psi^*$  is unique and stable in the sense that, starting from any initial distribution  $\psi_0$ , the sequence of distributions  $\{\psi_t\}$ ,

generated by  $g^w$ , converges weakly to  $\psi^*$ . This follows since the conditional-expectation equation (10) ensures enough mixing to apply Hopenhayn-Prescott's Theorem.<sup>13</sup> The monotonicity of the policy functions for continuation utility  $w$  seems intuitive and plausible, as illustrated by Examples 1 and 2.<sup>14</sup>

Another approach suggests uniqueness and convergence without relying on monotonicity. Grunwald, Hyndman, Tedesco and Tweedie (1999) show that one-dimensional, irreducible Markov processes with the Feller property that are bounded below and satisfy a CLAR condition, such as (10), have a unique and stable invariant distribution. Moreover, convergence to this distribution from any initial distribution is fast, in the sense that it occurs at the geometric rate  $\beta/\hat{\beta}$ . All the requirements of their theorem have been verified already for our model, except for the technical condition of irreducibility, which is likely to hold if we were to assume that the taste shock has a continuous distribution. We do not pursue this formally other than to note that the forces for reversion in (10) could be further exploited to establish uniqueness and convergence.

Our focus on steady states, where the distribution of utility entitlements replicates itself over time, has exploited the fact the relaxed and original planning problems then coincide. For the logarithmic utility case we can do more: we characterize transitional dynamics for any initial distribution of entitlements.

**Proposition 3 (a)** *If utility is logarithmic, then for any initial distribution of utility entitlements  $\psi$  there exists a value of  $e$  such that the solution to the relaxed and original social planning problem coincide. (b) Suppose two distributions of utility entitlements satisfy  $\psi^a > \psi^b$  in the sense of first-order stochastic dominance, then the associated endowments satisfy  $e_a > e_b$ .*

**Proof.** (a) Consider the relaxed social planning problem for some  $\hat{\lambda} = e^{-1}$ . We first show that its solution also solves the original social planning problem for any distribution  $\psi_0$  that satisfies  $\int k'(v; e)d\psi(v) = 0$ . We then show that there exists a value for  $\hat{\lambda} = e^{-1}$  for any initial distribution.

Since utility is unbounded below, we have  $k'(v_t) = \mathbb{E}_{t-1}[1 - \hat{\lambda}c'(u_t)]$ . Applying the law of iterated expectations to (10) then yields

$$\mathbb{E}_{-1}[1 - \hat{\lambda}c'(u_t^v(\theta^t))] = \left(\frac{\beta}{\hat{\beta}}\right)^t k'(v).$$

With logarithmic utility  $c'(u) = c(u)$ , so that  $\int k'(v)d\psi(v) = 0$  implies  $\int \mathbb{E}_{-1}c_td\psi = \hat{\lambda}^{-1} = e$  for all  $t = 0, 1, \dots$  The allocation is incentive compatible by Proposition 2 below, and applying part (c) of Theorem 2, it follows that it must solve the original planning problem.

Now consider any initial distribution  $\psi$ . We argue that we can find a value of  $\hat{\lambda} = e^{-1}$  such that  $\int k'(v; e)d\psi(v) = 0$ , and the result then follows immediately. We denote the value function for the

---

<sup>13</sup>See pg. 382-383 in Stokey, Lucas and Prescott (1989).

<sup>14</sup>Indeed, it can be shown that  $g^w(v, \theta)$  is strictly increasing in  $v$ . However, although we know of no counterexample, we have not found conditions that ensure the monotonicity of  $g^w(\theta, (\theta, v))$  for  $\theta \neq \underline{\theta}$ .

relaxed problem with  $\hat{\lambda} = e^{-1}$  by  $k(v; e)$ . The homogeneity of the sequential problem implies that the value function must satisfy

$$k(v; e) = \frac{1}{1 - \beta} \log(e) + k\left(v - \frac{1}{1 - \beta} \log(e); 1\right)$$

Note that  $k'(v - \log(e)/(1 - \beta); 1)$  is strictly increasing in  $e$  and limits to 1 and  $-\infty$  as  $e \rightarrow \infty$  and  $e \rightarrow -\infty$ , respectively. It follows that

$$\int k'(v; e) d\psi(v) = \int k'\left(v - \frac{1}{1 - \beta} \log(e); 1\right) d\psi(v) = 0 \quad (12)$$

defines a unique value of  $e$  for any initial distribution  $\psi_0$ .

(b) This part follows immediately from equation (12) which determines  $e$  by using the fact that  $k'(\cdot; 1)$  is a strictly decreasing function. ■

Perhaps of particular interest is the situation where the planning problem is modified to select the best initial distribution, instead of taking one as given. Then all initial dynasties are treated identically at the outset and started with the utility level  $v^*$  that solves  $k'(v^*) = 0$ . With logarithmic utility the social optimum then coincides with the solution to the relaxed problem. Then our previous discussion of convergence to a unique invariant distribution  $\psi^*$  can be reinterpreted in terms of the stability of the cross-sectional distribution in the population. If the Markov process  $\{v_t\}$  is stable then the cross-sectional distribution of welfare and consumption in the population will eventually settle down to the steady state.

The economic interest behind part (b) is that it implies that the solution to the planning problem is ex-post Pareto efficient in the following sense. Consider the optimal allocation that attains a distribution of entitlements  $\psi$  with some constant endowment level  $e$ . The proposition then implies that there is no alternative allocation that improves the social welfare criterion and creates a Pareto improvement among individuals in the current generation. That is, the optimal allocation also solves the original social planning problem modified to require  $U(\{c_t^v\}, \sigma^*; \beta) \geq v$  in place of  $U(\{c_t^v\}, \sigma^*; \beta) = v$ . Since this result holds for any distribution of entitlements it also holds for the distribution of continuation utilities implied by the optimal allocation in any period. Thus, in this sense, the optimal allocation is ex-post Pareto efficient.

## Sufficient Conditions for Verification

We conclude this section by describing sufficient conditions for a solution to the planning problem to exist at the steady state  $\psi^*$  identified by the policy functions in Proposition 2. This involves two steps. First, we establish that allocations generated by the policy functions are indeed incentive compatible by verifying the condition in part (c) of Theorem 2. Second, we verify that average consumption is finite under the invariant distribution  $\psi^*$ .

**Lemma 2** *The allocation generated from the policy functions  $(g^u, g^w)$ , starting from any  $v_0$ , is guaranteed to be incentive compatible in the following cases: (a) utility is bounded above; (b) utility is bounded below; (c) utility is logarithmic; or (d)  $\bar{\gamma} < 1$  or  $\underline{\gamma} > 0$ .*

**Proof.** (a) If utility is also bounded below, then the result follows from part (b). So suppose utility is unbounded below, but bounded above. Then  $k'(g^w(\bar{\theta}, \cdot))$  is continuous and Proposition 1 implies that  $\lim_{v \rightarrow -\infty} k'(g^w(\bar{\theta}, v)) = 1$ . It follows that  $\max_v k'(g^w(\bar{\theta}, v))$  is attained, so there exists a  $v_L > -\infty$  such that  $g^w(\bar{\theta}, v) > v_L$ .

(b) If utility is bounded below, the result follows immediately from part (c) of Theorem 2.

(c) Using the first-order conditions from the proof of Proposition 1, one can show that:

$$\frac{c'(u(\bar{\theta}))}{c'(u(\underline{\theta}))} \leq \frac{\bar{\theta}}{\underline{\theta}}.$$

With logarithmic utility this implies that  $g^u(\bar{\theta}, v) - g^u(\underline{\theta}, v) \leq \log(\bar{\theta}/\underline{\theta})$ . The incentive constraint then implies that  $g^w(\underline{\theta}, v) - g^w(\bar{\theta}, v) \leq (\bar{\theta}/\beta) \log(\bar{\theta}/\underline{\theta}) \equiv A$ . It follows that  $v_t(\hat{\theta}^{t-1}) \geq v_t(\theta^{t-1}) - tA$  for all pairs of histories  $\theta^{t-1}$  and  $\hat{\theta}^{t-1}$ . Then

$$\beta^t \mathbb{E}_{-1}[v_t(\sigma^{t-1}(\theta^{t-1}))] \geq \beta^t \mathbb{E}_{-1}[v_t(\theta^{t-1})] - \beta^t tA.$$

From part (b) of Theorem 2 we have  $\lim_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1}[v_t(\theta^{t-1})] = 0$ . Since  $\lim_{t \rightarrow \infty} \beta^t tA = 0$ , it follows that  $\limsup_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1}[v_t(\sigma^{t-1}(\theta^{t-1}))] \geq 0$ .

(d) If  $\underline{\gamma} > 0$  then the bound in (11) implies that  $k'(g^w(\bar{\theta}, v)) \geq 1 - \beta/\hat{\beta}$  and the result follows immediately. If  $\bar{\gamma} < 1$ , then we can define  $\kappa = 1 - (1 - \beta/\hat{\beta})/(1 - \bar{\gamma})$ , and define  $v_H$  by  $k'(v_H) = \kappa$ . Then for all  $v \leq v_H$  we have  $g^w(\theta, v) \leq v$ . It follows that the unique ergodic set is bounded above by  $v_H$ . We can now apply the argument in (a) so there exists a  $v_L > -\infty$  such that  $g^w(\bar{\theta}, v) > v_L$ .

■

We now find sufficient conditions that guarantee average consumption is finite under the invariant distribution  $\psi^*$ . If the ergodic set for utility  $v$  is bounded away from the extremes, then consumption is bounded and average consumption is trivially finite. Even when a bounded ergodic set for utility  $v$  cannot be ensured, finite average consumption can be guaranteed for a large class of utility functions.

**Lemma 3** *Average consumption is finite under the invariant distribution  $\psi^*$*

$$\int \sum_{\theta} c(g^u(\theta, v)) p(\theta) d\psi^*(v) < \infty$$

*if either (a) the ergodic set for  $v$  is bounded; or (b) utility is such that  $c'(u(c))$  is a convex function of  $c$ .*

**Proof.** Part (a) is immediate since by continuity of the policy functions, consumption is bounded. For part (b), recall that  $\int k'(v) d\psi^*(v) = 0$  under the invariant distribution  $\psi^*$ . If utility is un-

bounded below then all solutions for consumption are interior. If utility is bounded below, then corner solutions with  $g^c(\theta, v) = 0$  for some  $\theta$  can only occur for low enough levels of  $v$ , so that  $g^c(\theta, v)$  is bounded, for all  $\theta$  in this compact set. Recall that for interior solutions

$$1 - k'(v) = \hat{\lambda} \mathbb{E}[c'(g^u(\theta, v))] = \hat{\lambda} \mathbb{E}[c'(u(c(g^u(\theta, v))))]$$

Applying Jensen's inequality we obtain

$$c' \left( u \left( \int \mathbb{E}[c(g^u(\theta, v))] d\psi^*(v) \right) \right) \leq \int \mathbb{E}[c'(u(c(g^u(\theta, v))))] d\psi^*(v) = 1.$$

The result then follows since  $c'(u(c))$  is an increasing function of  $c$ . ■

Note that a bounded ergodic set is guaranteed by  $\bar{\gamma} < 1$ , which is ensured for taste shocks with sufficiently small amplitude; and condition (b) holds, for example, for all constant relative risk aversion utility functions with  $\sigma \geq 1$ .

The value of average consumption depends on the value of  $\hat{\lambda}$ . For instance, in the case of constant relative risk aversion utility, average steady state consumption is a power function of  $\hat{\lambda}$ , and thus has full range. In fact, in this case the entire solution for consumption is homogenous of degree one in the value of the endowment  $e$ . This ensures a steady state solution to the social planning problem for any endowment level.

## 5 Discussion: Mean-Reversion

This section develops an intuitive understanding of the key mean-reversion property discussed previously. We first derive the impulse response of consumption to a one-time taste shock. We then revisit the full problem with an alternative Bellman equation that is useful as a source of intuition.

### Impulse Response

Consider a version of our model where only the first generation faces uncertainty. In the first period, there are two possible values for the taste shock  $\theta_0 \in \{\theta_L, \theta_H\}$ , but thereafter the economy is deterministic:  $\theta_t = 1$  for  $t \geq 1$ . We compare this to the case with no uncertainty in the first period. This allows us to trace out the consumption response to the taste shock over time. To simplify, we adopt logarithmic utility.

We begin by studying a subproblem of the deterministic planning problem from the second generation onward, that is for  $t = 1, 2, \dots$ . For a given, promised continuation utility  $v_1$ , the planning problem is

$$k_{\text{det}}(v_1) \equiv \max_{\{c_t\}} \sum_{t=1}^{\infty} \hat{\beta}^{t-1} \left( \log c_t - \hat{\lambda} c_t \right),$$

subject to

$$v_1 = \sum_{t=1}^{\infty} \beta^{t-1} \log c_t.$$

The associated Bellman equation is

$$k_{\text{det}}(v_t) = \max_{c_t, v_{t+1}} \left( \log(c_t) - \hat{\lambda} c_t + \hat{\beta} k_{\text{det}}(v_{t+1}) \right)$$

subject to  $v_t = \log c_t + \beta v_{t+1}$ . The first-order and envelope conditions imply that

$$k'_{\text{det}}(v_{t+1}) = \frac{\beta}{\hat{\beta}} k'_{\text{det}}(v_t), \quad (13)$$

$$c_t = \hat{\lambda}^{-1} (1 - k'_{\text{det}}(v_t)). \quad (14)$$

Condition (13) shows that  $\{k'_{\text{det}}(v_t)\}$  reverts geometrically towards zero at the rate  $\beta/\hat{\beta}$ . This is a deterministic version of the conditional-expectation equation (10). In the logarithmic case, it translates directly into consumption by the first-order condition (14). Thus, consumption reverts back to a common steady state at the same rate; deviations from the steady-state level of consumption have a half-life of  $(\log_2(\hat{\beta}/\beta))^{-1}$ . Note that in the Atkeson-Lucas case when social and private discounting coincide, so that  $\beta = \hat{\beta}$ , consumption remains perfectly constant after the shock at its new level  $c_t = c(v_1/(1-\beta))$ .

Turning to the first generation at  $t = 0$ , the planning problem solves

$$\max_{u_0, v_1} \mathbb{E}[\theta_0 \log(c_0(\theta_0)) - \hat{\lambda}_0 c_0(\theta_0) + \hat{\beta} k_{\text{det}}(v_1(\theta_0))]$$

subject to

$$\theta_L \log(c_0(\theta_L)) + \beta v_1(\theta_L) \geq \theta_H \log(c_0(\theta_H)) + \beta v_1(\theta_H).$$

where we omit the other incentive constraint since it is not binding at the optimum, and the problem is convex. At the optimum,  $c_0(\theta_H) > c_0(\theta_L)$ ,  $v_1(\theta_H) < v_1(\theta_L)$ , and

$$\mathbb{E}[k'_{\text{det}}(v_1(\theta))] = 0,$$

implying that  $v_1(\theta_H) < v^* < v_1(\theta_L)$  where  $k'(v^*) = 0$ . Note that average consumption is constant and equal to  $\hat{\lambda}^{-1}$  in all periods.

Figure 4 shows the consumption response to a taste shock in the first period, for subsequent periods. That is, we use (13) and (14) for  $t \geq 1$  starting at  $v_1(\theta_L)$ ,  $v^*$  and  $v_1(\theta_H)$ . The effect on consumption from the shock dies out over time and consumption returns to a common steady-state level. Again, this illustrates that the influence of past fortunes eventually vanishes for distant descendants. We also plot the Atkeson-Lucas case with  $\beta = \hat{\beta}$ , where the luck of the first generation has a permanent impact on the consumption of all descendants.

To provide incentives for the first generation, society rewards the descendants of an individual

Figure 4: Consumption path for  $t \geq 1$  in response to taste shock at  $t = 0$

reporting a low taste shock. Rewards can take two forms and society makes use of both. The first is standard and involves increased consumption spending, in present-value terms. The second is more subtle and exploits differences in preferences: it allows an adjustment in the pattern of consumption, for a given present value, in the direction preferred by individuals.<sup>15</sup>

Since individuals are more impatient than the planner, this latter form of reward is delivered by tilting the consumption profile toward the present. Similarly, punishments involve tilting the consumption path toward the future. In both cases, earlier consumption dates are used more intensively to provide incentives — rewards and punishments are front-loaded. Indeed, consumption returns to a common steady-state level in the long-run regardless of the initial shock because affecting the consumption of very distant descendants is not an efficient way for society to provide incentives to the first generation.

## Another Bellman Equation

Here we develop another Bellman equation that holds for any value of  $q$  not necessarily equal to  $\hat{\beta}$ . This alternative formulation is useful, both as a source of intuition and to motivate our focus on  $q = \hat{\beta}$ .

Consider the following cost minimization problem

$$K(v, \hat{v}) \equiv \min_c \sum_{t=0}^{\infty} q^t \sum_{\theta^t} c_t(\theta^t) \Pr(\theta^t),$$

<sup>15</sup>Some readers may recognize this last method as the time-honored system of rewards and punishments used by parents when conceding their child's favorite snack or reducing their TV-time. In these instances, the child values some goods more than the parent wishes, and the parent uses them to provide incentives.

subject to the incentive compatibility constraint  $U(\{c_t\}, \sigma^*; \beta) \geq U(\{c_t\}, \sigma; \beta)$  and

$$\begin{aligned}\hat{v} &= \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u(c_t)] \\ v &= \sum_{t=0}^{\infty} \beta^t \mathbb{E}_{-1} [\theta_t u(c_t)],\end{aligned}$$

while delivering utility  $\hat{v}$  and  $v$  for the planner and individual, respectively. Then the value function must satisfy the Bellman equation

$$K(v, \hat{v}) = \max_{u, w, \hat{w}} \mathbb{E}[c(u(\theta)) + qK(w(\theta), \hat{w}(\theta))],$$

subject to

$$\begin{aligned}\hat{v} &= \mathbb{E}[\theta u(\theta) + \hat{\beta} \hat{w}(\theta)] \\ v &= \mathbb{E}[\theta u(\theta) + \beta w(\theta)]\end{aligned}$$

and

$$\theta u(\theta) + \beta w(\theta) \geq \theta u(\theta') + \beta w(\theta') \text{ for all } \theta, \theta' \in \Theta.$$

This formulation could be used to derive all of our results, although the lower-dimensional Bellman equation (7) is slightly more convenient for that purpose. The advantage of this cost-minimization formulation, however, is that it lends itself naturally to economic interpretations.

The following story provides a useful reinterpretation and source for intuition. Consider an infinite-lived household with two members, husband and wife, and assume that consumption is a public good — there is no intra-period resource allocation problem. However, husband and wife disagree on how to discount the future. Suppose the wife is more patient, but only the husband can observe and report taste-shock realizations.

Then this cost-minimization problem characterizes the constrained Pareto problem for this household, in the sense that the isocost curve  $K(v, \hat{v}) = K_0$  represents, given resources  $K_0$ , the Pareto frontier between husband and wife. The Pareto frontier is non-standard in that it is not everywhere decreasing and does not represent the usual transfer of private goods between two agents. Instead, it arises from differences in preferences that generate a disagreement about the optimal consumption path for the only public good. Since disagreement on preferences is bounded, the Pareto frontier is non-monotone and the highest possible utility for the wife is attained for an interior utility level for the husband, where  $K_1(v^*, \hat{v}^*) = 0$ . Reductions in the husband's utility to the left of this point must also decrease utility for the wife, for a given level of resources.

The first-order conditions can be rearranged to deliver

$$\hat{\beta} K_2(v, \hat{v}) = q K_2(w(\theta), \hat{w}(\theta)) \tag{15}$$

$$-\frac{K_1(v, \hat{v})}{K_2(v, \hat{v})} = \frac{\beta}{\hat{\beta}} \mathbb{E} \left[ -\frac{K_1(w(\theta), \hat{w}(\theta))}{K_2(w(\theta), \hat{w}(\theta))} \right]. \quad (16)$$

Condition (15) can then be used to argue that a steady-state requires  $q = \hat{\beta}$ . Indeed, if  $q < \hat{\beta}$ , then  $\{K_{2t}\}$  would increase without bound; likewise, if  $q > \hat{\beta}$ , then  $\{K_{2t}\}$  decreases toward zero. Both situations clearly do not lend themselves to the existence of an invariant distribution for  $(v, \hat{v})$ . On the other hand, if  $q = \hat{\beta}$  then  $K_2(v_t, \hat{v}_t)$  is constant along the optimal path and an invariant distribution is possible.

When  $q = \hat{\beta}$ , the state  $(v_t, \hat{v}_t)$  moves along a one-dimensional locus given by  $K_2(v, \hat{v}) = K_2(v_0, \hat{v}_0)$ . Intuitively, since no incentives are required for the wife, she is perfectly insured in the sense that the marginal cost of delivering welfare to her is held constant across time.

Figure 5: Isocost curves of  $K(v, \hat{v})$

Figure 5 shows that the curve  $K_2(v, \hat{v}) = K_2(v_0, \hat{v}_0)$  for continuation utilities cuts the isocost curves from below, and cuts  $K_1(v, \hat{v}) = 0$  from above. Intuitively, incentives require foregoing perfect insurance for the husband and accepting fluctuations in  $v$  as rewards and punishments. Starting from  $(v^*, \hat{v}^*)$ , rewards can be delivered in two ways. The optimum makes use of both forms of rewards, explaining the shape of the schedule for continuation utilities.

The first form of rewarding involves increasing resources  $K$ , and can be seen as an upward movement along the diagonal  $K_1(v, \hat{v}) = 0$ . However, the husband is also rewarded by allowing an allocation of these resources that is more to his liking, which can be represented as lateral movements along the Pareto frontier, which at  $(v^*, \hat{v}^*)$  is horizontally flat. The solution combines both forms of rewards and, as a result,  $(v, \hat{v})$  travels along  $K_2(v, \hat{v}) = K_2(v_0, \hat{v}_0)$  to the right of  $K_1(v, \hat{v}) = 0$  and above the initial isocost curve.

Condition (16) is the analog of the conditional-expectation equation (10) obtained from the one-dimensional Bellman equation. Here, it implies that the slope of the isocost curve (Pareto frontier),  $-K_1/K_2$  reverts geometrically toward 0. Thus,  $(v_t, \hat{v}_t)$  moves along  $K_2(v, \hat{v}) = K_2(v_0, \hat{v}_0)$  and eventually reverts toward  $(v^*, \hat{v}^*)$ . Intuitively, the solution deviates from  $(v^*, \hat{v}^*)$  to provide the husband with incentives, but it is efficient to revert back to this point of maximum efficiency for the wife: Patience ensures that the wife has her way in the long-run.

## 6 Estate Taxation

We now turn to a repeated Mirrleesian economy and study optimal taxation. In this version of our model, individuals have identical preferences over consumption and work effort but are heterogenous regarding their labor productivity, which is privately observed by the individual and independently distributed across generations and dynasties. We continue to focus on the case where the social welfare criterion discounts the future at a lower rate than individuals.

Unlike the taste-shock model, here even if we were to restrict allocations to feature no link between parent and child, there would still be a non-trivial planning problem. Indeed, in each period the situation would then be identical to the static, nonlinear income tax problem originally studied by Mirrlees (1971). Moreover, in the absence of altruism, so that  $\beta = 0$ , the social optimum actually coincides with this static solution. With altruism, however, we shall see below that it is always optimal to link welfare across generations within a dynasty to enhance incentives for parents.

Despite differences between the Mirrleesian economy and our taste-shock model, our previous analysis can be adapted virtually without change. In particular, a recursive representation can be derived, and the Bellman equation can be used to characterize the solution and to establish that a steady-state, invariant distribution exists. This highlights the fact that our model requires asymmetric information, but not any particular form of it.

We focus on an implementation of the allocation that uses income and estate taxes, and derive some interesting results for the latter. We find that estate taxation should be progressive: more fortunate parents should face a higher average marginal tax rate on their bequests. This result reflects the mean reversion in consumption explained in the previous section. A higher estate tax ensures that the fortunate face a lower net rate of return across generations, and that consequently their consumption path decreases over time toward the mean.

### Repeated Mirrlees: Productivity Shocks

Each period of this economy is identical to the canonical optimal taxation setup in Mirrlees (1971). Utility depends on the level of consumption  $c$  and work effort  $n$ . We assume that individuals in generation  $t$  have identical preferences that satisfy

$$V_t = \mathbb{E}_{t-1}[u(c_t) - h(n_t) + \beta V_{t+1}],$$

but differ regarding their productivity in translating work effort into output. An individual with productivity  $w$ , exerting work effort  $n$ , produces output  $y = wn$ . We assume that productivity  $w$  is independently and identically distributed across dynasties and generations. Thus, the productivity talents of parent and child are unrelated — innate skills are assumed nonheritable. Given this assumption, if the optimum features intergenerational transmission of welfare, then it represents a social decision to provide altruistic parents with incentives in this way, and not a mechanical result originating from the assumed physical environment.<sup>16</sup>

For convenience, we adopt the power disutility function  $h(n) = n^\gamma/\gamma$  so that, defining  $\theta \equiv w^{-\gamma}$ , we can write total utility over consumption and output as being subject to taste shocks

$$\sum_{t=0}^{\infty} \beta^t \mathbb{E}_{-1} [u(c_t) - \theta_t h(y_t)] = \sum_{t=1}^{\infty} \beta^t \mathbb{E}_{-1} [\beta^{-1} u(c_{t-1}) - \theta_t h(y_t)] - \mathbb{E}_{-1} [\theta_0 h(y_0)]$$

The right-hand side of this equation leads to a convenient recursive representation of the planning problem in the continuation utility defined by  $v_t = \sum_{s=0}^{\infty} \beta^s \mathbb{E}_{t-1} [u(c_{t+s-1}) - \theta_{t+s} h(y_{t+s})]$  — where we are abusing notation slightly by folding the  $\beta^{-1}$  into the definition of the utility function  $u(c)$ .

The resource constraint requires total consumption not to exceed total output plus some fixed constant endowment

$$\int \sum_{\theta^t} c_t^v(\theta^t) \Pr(\theta^t) d\psi(v) \leq \int \sum_{\theta^t} y_t^v(\theta^t) \Pr(\theta^t) d\psi(v) + e,$$

where individuals are indexed by their initial utility entitlement  $v$ , with distribution  $\psi$  in the population.

We continue to assume social discounting is lower than private discounting:  $\hat{\beta} > \beta$ . The planning problem is to choose an allocation  $\{c_t^v(\theta^t), y_t^v(\theta^t)\}$  to maximize average social welfare subject to the incentive-compatibility constraints and the resource constraints.

Using the last expression for the utility function and applying similar reasoning as in the taste-shock model yields the Bellman equation for the associated relaxed problem

$$k(v) = \max_{u_-, h, w} \mathbb{E}[u_- - \hat{\lambda}c(u_-) - \theta h(\theta) + \hat{\lambda}y(h(\theta)) + \hat{\beta}k(w(\theta))]$$

$$\begin{aligned} v &= \mathbb{E}[u_- - \theta h(\theta) + \beta w(\theta)] \\ -\theta h(\theta) + \beta w(\theta) &\geq -\theta h(\theta') + \beta w(\theta'), \end{aligned}$$

where the function  $y(h)$  represents the inverse of the disutility function,  $y = h^{-1}$ . The arguments that justify the study of this Bellman equation, are similar to those that underlie Theorems 1 and 2 in the context of the taste-shock model. The results regarding steady states parallel those obtained previously, and imply that an invariant distribution exists with no immiseration, as in Proposition

---

<sup>16</sup>As in the taste shock model, here the case with  $\beta = \hat{\beta}$  leads to immiseration. This case has been studied by Albanesi and Sleet (2004), who impose an exogenous lower bound on dynamic welfare to circumvent immiseration.

## Implementation with Income and Estate Taxation

Any allocation that is incentive compatible and feasible can be implemented by a combination of taxes on labor income and estates. Here we first describe this implementation, and explore some features of the optimal estate tax in the next subsection.

For any incentive-compatible and feasible allocation  $\{c_t^v(\theta^t), y_t^v(\theta^t)\}$  we propose an implementation along the lines of Kocherlakota (2004). In each period, conditional on the history of their dynasty's reports  $\hat{\theta}^{t-1}$  and any inherited wealth, individuals report their current shock  $\hat{\theta}_t$ , produce, consume, pay taxes and bequeath wealth subject to the following set of budget constraints

$$c_t + b_t \leq y_t(\hat{\theta}^t) - T_t(\hat{\theta}^t) + (1 - \tau_t(\hat{\theta}^t))R_{t-1,t}b_{t-1} \quad t = 0, 1, \dots \quad (17)$$

where  $R_{t-1,t}$  is the before-tax interest rate across generations, and initially  $b_{-1} = 0$ . Individuals are subject to two forms of taxation: a labor income tax  $T_t(\hat{\theta}^t)$ , and a proportional tax on inherited wealth  $R_{t-1,t}b_{t-1}$  at rate  $\tau_t(\hat{\theta}^t)$ .<sup>17</sup>

Given a tax policy  $\{T_t^v(\theta^t), \tau_t^v(\theta^t), y_t^v(\theta^t)\}$ , an equilibrium consists of a sequence of interest rates  $\{R_{t,t+1}\}$ ; an allocation for consumption, labor income and bequests  $\{c_t^v(\theta^t), b_t^v(\theta^t)\}$ ; and a reporting strategy  $\{\sigma_t^v(\theta^t)\}$  such that: (i)  $\{c_t, b_t, \sigma_t\}$  maximize dynamic utility subject to (17), taking the sequence of interest rates  $\{R_{t,t+1}\}$  and the tax policy  $\{T_t, \tau_t, y_t\}$  as given; and (ii) the asset market clears so that  $\int \mathbb{E}_{-1}[b_t^v(\theta^t)]d\phi(v) = 0$  for all  $t = 0, 1, \dots$  We say that a competitive equilibrium is incentive compatible if, in addition, it induces truth telling.

For any feasible, incentive-compatible allocation  $\{c_t^v, y_t^v\}$ , we construct an incentive-compatible competitive equilibrium with no bequests by setting  $T_t^v(\theta^t) = y_t(\theta^t) - c_t(\theta^t)$  and

$$\tau_t^v(\theta^t) = 1 - \frac{1}{\beta R_{t-1,t}} \frac{u'(c_{t-1}^v(\theta^{t-1}))}{u'(c_t^v(\theta^t))} \quad (18)$$

for any sequence of interest rates  $\{R_{t-1,t}\}$ . These choices work because the estate tax ensures that for any reporting strategy  $\sigma$ , the consumption allocation  $\{c_t^v(\sigma^t(\theta^t))\}$  satisfies the consumption Euler equation

$$u'(c_t^v(\sigma^t(\theta^t))) = \beta R_{t,t+1} \sum_{\theta_{t+1}} u'(c_{t+1}^v(\sigma^{t+1}(\theta^t, \theta_{t+1}))) (1 - \tau_{t+1}^v(\sigma^{t+1}(\theta^t, \theta_{t+1}))) \Pr(\theta_{t+1}),$$

and the labor income tax is such that the budget constraints are satisfied with this consumption allocation and no bequests,  $b_t^v(\theta^t) = 0$ . Thus, this no-bequest choice is optimal for the individual

---

<sup>17</sup>In this formulation, taxes are a function of the entire history of reports, and labor income  $y_t$  is mandated given this history. However, if the labor income histories  $y^t : \Theta^t \rightarrow \mathbb{R}^t$  being implemented are invertible, then by the taxation principle we can rewrite  $T$  and  $\tau$  as functions of this history of labor income and avoid having to mandate labor income. Under this arrangement, individuals do not make reports on their shocks, but instead simply choose a budget-feasible allocation of consumption and labor income, taking as given prices and the tax system.

regardless of the reporting strategy followed. Since the resulting allocation is incentive compatible, by hypothesis, it follows that truth telling is optimal. The resource constraints together with the budget constraints then ensure that the asset market clears.<sup>18</sup>

As noted above, in our economy without capital only the after-tax interest rate matters so the implementation allows any equilibrium before-tax interest rate  $\{R_{t-1,t}\}$ . In the next subsection, we set the interest rate to the reciprocal of the social discount factor,  $R_{t-1,t} = \hat{\beta}^{-1}$ . This choice is natural because it represents the interest rate that would prevail at the steady state in a version of our economy with capital.

## Optimal Progressive Estate Taxation

In this subsection we derive an important intertemporal condition that must be satisfied by the optimal allocation. This condition has interesting implications for the optimal estate tax, computed using (18) at the optimal allocation.

Let  $\lambda$  be the multiplier on the promise-keeping constraint and let  $\mu(\theta, \theta')$  represent the multipliers on the incentive constraints. Then the first-order conditions for  $u_-$  and  $w(\theta)$  are

$$\begin{aligned} c'(u_-) - \hat{\lambda} - \lambda &= 0 \\ \hat{\beta}k'(w(\theta))p(\theta) - \beta\lambda p(\theta) - \sum_{\theta'} \mu(\theta, \theta') + \sum_{\theta'} \mu(\theta', \theta) &= 0 \end{aligned}$$

and the envelope condition is  $k'(v) = \lambda$ . Together these imply

$$\sum_{\theta} k'(w(\theta))p(\theta) = \frac{\beta}{\hat{\beta}}k'(v),$$

Using  $c'(u_-) = 1/u'(c_-) = \hat{\lambda} + k'(v)$  we arrive at the *Modified Inverse Euler equation*

$$\frac{1}{u'(c_-)} = \frac{\hat{\beta}}{\beta} \sum_{\theta} \frac{1}{u'(c(\theta))} p(\theta) - \hat{\lambda} \left( \frac{\hat{\beta}}{\beta} - 1 \right). \quad (19)$$

The left-hand side together with the first term on the right-hand side is the standard inverse Euler equation. The second term on the right-hand side is novel, since it is zero when  $\beta = \hat{\beta}$  and is strictly negative when  $\hat{\beta} > \beta$ .<sup>19</sup>

In our environment, the relevant past history is encoded in the continuation utility so the estate tax  $\tau(\theta^{t-1}, \theta_t)$  can actually be reexpressed as a function of  $v_t(\theta^{t-1})$  and  $\theta_t$ . Abusing notation we then denote the estate tax by  $\tau_t(v, \theta_t)$ . Since we focus on the steady-state, invariant distribution, we also drop the time subscripts and write  $\tau(v, \theta)$ .

<sup>18</sup>Since the consumption Euler equation holds with equality, the same estate tax can be used to implement allocations with any other bequest plan with income taxes that are consistent with the budget constraints.

<sup>19</sup>This equation can also be derived from an elementary variation argument. This is done in Farhi, Kocherlakota and Werning (2005), who also show that this equation, and its implications for estate taxation, generalize to an economy with capital and an arbitrary process for skills.

The average estate tax rate  $\bar{\tau}(v)$  is then defined by

$$1 - \bar{\tau}(v) \equiv \sum_{\theta} (1 - \tau(v, \theta)) p(\theta) \quad (20)$$

Using the modified inverse Euler equation (19) we obtain

$$\bar{\tau}(v) = -\hat{\lambda} u'(c_-(v)) \left( \frac{\hat{\beta}}{\beta} - 1 \right)$$

In particular, this implies that the average estate tax rate is negative,  $\bar{\tau}(v) < 0$ , so that bequests are subsidized. However, recall that before-tax interest rates are not uniquely determined in our implementation. As a consequence, neither are the estate taxes computed by (18). With our particular choice for the before-tax interest rate, however, the tax rates are pinned down and acquires a corrective, Pigouvian role. Differences in discounting can be interpreted as a form of externalities from future consumption, and the negative average tax can then be seen as a way of countering these externalities as prescribed by Pigou. In our setup without capital, this result depends on the choice of the before-tax interest rate. However, the negative tax on estates would be a robust steady-state outcome in a version of our economy with capital.

In our model it is more interesting to understand how the average tax varies with the history of past shocks encoded in the promised continuation utility  $v$ . The average tax is an increasing function of consumption, which, in turn, is an increasing function of  $v$ . Thus, estate taxation is progressive: the average tax on transfers for more fortunate parents is higher.

**Proposition 4** *In the repeated Mirrlees economy, the optimal allocation can be implemented by a combination of income and estate taxes. At a steady-state, invariant distribution  $\psi^*$ , the optimal average estate tax  $\bar{\tau}(v)$  defined by (18) and (20) is increasing in promised continuation utility  $v$ .*

The progressivity of the estate tax reflects the mean-reversion in consumption. The fortunate must face lower net rates of return so that their consumption path decreases towards the mean.<sup>20</sup>

## 7 Conclusions

Should privately-felt parental altruism affect the social contract? If so, what are the long-run implications for inequality? To address these questions, we model a central tension in society: the tradeoff between ensuring equality of opportunity for newborns and providing incentives for altruistic parents.

Our model's answer is that society should indeed exploit altruism to motivate parents, linking the welfare of children to that of their parents. However, we also find that if we value the welfare of future generations directly, the inheritability of good or bad fortune should be tempered. This

---

<sup>20</sup>Farhi, Kocherlakota and Werning (2005) explore more general versions of this result and discuss several related intuitions.

produces a steady-state outcome in which welfare and consumption are mean-reverting, long-run inequality is bounded, social mobility is possible and misery is avoided by everyone.

What instruments should society use to implement such allocations? For a Mirrleesian version of our model we find an important role for the estate tax. The optimal tax on inheritances is progressive: more fortunate parents should face a higher average marginal tax rate on their bequests. This result illustrates an interesting way in which the conflict between corrective and redistributive taxation is optimally resolved. Further examination of other situations with similar conflicts remains an interesting direction for future work.<sup>21</sup>

## Appendix

### Proof of Theorem 1

Weak concavity of the value function  $k(v)$  follows because the relaxed sequence problem has a concave objective and a convex constraint set. The weak concavity of the value function  $k(v)$  implies its continuity over the interior of its domain. If utility is bounded, continuity at the extremes can also be established as follows. Define the first-best value function

$$k^*(v) \equiv \max_u \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t) - \hat{\lambda} c(u_t(\theta^t))]$$

subject to  $v = \sum_{t=0}^{\infty} \beta^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t)]$ . Then  $k^*(v)$  is continuous and  $k(v) \leq k^*(v)$ , with equality at any finite extremes  $\bar{v}$  and  $\underline{v}$ . Then continuity of  $k(v)$  at finite extremes follows. Thus,  $k(v)$  is continuous.

The constraint (6) with  $q = \hat{\beta}$  implies that utility and continuation utility are well-defined. Toward a contradiction, suppose

$$\lim_{T \rightarrow \infty} \sum_{t=0}^T \beta^t E_s \theta_t u(c_t)$$

is not defined, for some  $s \geq -1$ . This implies that  $\lim_{T \rightarrow \infty} \sum_{t=0}^T \beta^t \max(E_s \theta_t u(c_t), 0) = \infty$ . Since utility is concave  $\theta u(c) \leq Ac + B$  for some  $A, B > 0$ , so it follows that

$$\sum_{t=0}^T \beta^t \max(E_s \theta_t u(c_t), 0) \leq A \sum_{t=0}^T \beta^t \mathbb{E}_s c_t + B \leq A \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_s c_t + B$$

Taking the limit yields  $\lim_{T \rightarrow \infty} \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} c_t = \infty$ . Since there are finitely many histories  $\theta^s \in \Theta^{s+1}$  this implies  $\lim_{T \rightarrow \infty} \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} c_t = \infty$ . If there is a non-zero measure of such agents this implies a contradiction of (6). Thus, for both the relaxed and unrelaxed problems utility and continuation utility are well defined given the other constraints on the problem. This is important for our recursive formulation below.

---

<sup>21</sup>Some progress along these lines can be found in Amador, Angeletos and Werning (2005).

We next prove two lemmas that imply the rest of the theorem. Consider the optimization problem on the right hand side of the Bellman equation:

$$\sup_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda}c(u(\theta)) + \hat{\beta}k(w(\theta))] \quad (21)$$

$$v = \mathbb{E}[\theta u(\theta) + \beta w(\theta)] \quad (22)$$

$$\theta u(\theta) + \beta w(\theta) \geq \theta u(\theta') + \beta w(\theta') \text{ for all } \theta, \theta' \in \Theta \quad (23)$$

Define  $m \equiv \max_{c \geq 0, \theta \in \Theta} (\theta u(c) - \hat{\lambda}c)$  and  $\hat{k}(v) \equiv k(v) - m/(1 - \hat{\beta}) \leq 0$ . The problem in (21) is equivalent to the following optimization with non-positive objective:

$$\sup_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda}c(u(\theta)) - m + \hat{\beta}\hat{k}(w(\theta))] \quad (24)$$

subject to (22) and (23).

**Lemma 1** *The supremum in (21), or equivalently (24), is attained.*

**Proof.** If utility is bounded the result follows immediately by continuity of the objective function and compactness of the constraint set. So suppose utility is unbounded above and below — similar arguments apply when utility is only unbounded below or only unbounded above. We first show that

$$\lim_{v \rightarrow \infty} \hat{k}(v) = \lim_{v \rightarrow -\infty} \hat{k}(v) = -\infty \quad (25)$$

and then use this result to restrict, without loss, the optimization within a compact set, ensuring a maximum is attained.

To establish these limits, define

$$h(v, \hat{\beta}) \equiv \sup_u \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1}[\theta_t u(\theta^t) - \hat{\lambda}c(u(\theta^t)) - m]$$

subject to  $v = \mathbb{E}_{-1} \sum_{t=0}^{\infty} \hat{\beta}^t \theta_t u(\theta^t)$ . Since this corresponds to the same problem but without the incentive constraints it follows that  $\hat{k}(v) \leq h(v, \hat{\beta})$ . If  $\lim_{v \rightarrow \infty} h(v, \hat{\beta}) = \lim_{v \rightarrow -\infty} h(v, \hat{\beta}) = -\infty$ , then the desired limits (25) follow. Since  $\theta u - \hat{\lambda}c(u) - m \leq 0$  and  $\beta < \hat{\beta}$  it follows that

$$h(v, \hat{\beta}) \leq h(v, \beta) = v - \hat{\lambda}C(v, \beta) - \frac{m}{1 - \beta}, \quad (26)$$

where

$$C(v, \beta) \equiv \inf_u \sum_{t=0}^{\infty} \beta^t \mathbb{E}_{-1} c(u(\theta^t))$$

subject to  $v = \sum_{t=0}^{\infty} \beta^t \mathbb{E}_{-1} [\theta_t u(\theta^t)]$ . Note that  $C(v, \beta)$  is a standard convex first-best allocation problem, with solution  $u(\theta^t) = (c')^{-1}(\theta_t \gamma(v))$  for some positive multiplier  $\gamma(v)$ , increasing in  $v$  and

such that  $\lim_{v \rightarrow -\infty} \gamma(v) = 0$  and  $\lim_{v \rightarrow \infty} \gamma(v) = \infty$ . Then

$$C(v, \beta) = \frac{1}{1-\beta} \mathbb{E} \left[ c \left( (c')^{-1} (\theta \gamma(v)) \right) \right],$$

so that  $\lim_{v \rightarrow -\infty} h(v, \beta) = -\infty$  and  $\lim_{v \rightarrow \infty} h(v, \beta) = -\infty$ . Using the inequality (26) this establishes  $\lim_{v \rightarrow -\infty} h(v, \hat{\beta}) = -\infty$  and  $\lim_{v \rightarrow \infty} h(v, \hat{\beta}) = -\infty$ , which, in turn, imply the limits (25).

Fix a  $v$ . Take any allocation that verifies the constraints (22) and (23) and let  $\bar{k} < \infty$  be the corresponding value of (24). Then, since the objective is non-positive, we can restrict the maximization to  $w(\theta)$  such that  $\hat{k}(w(\theta)) \geq \bar{k}/(\hat{\beta} p(\theta))$ . Since  $\hat{k}(w(\theta))$  is concave with the limits (25), this defines a closed, bounded interval for  $w(\theta)$ , for each  $\theta$ . It follows that there exists  $M_{v,w} < \infty$  such that we can restrict the maximization to  $|w(\theta)| \leq M_{v,w}$ .

Similarly, we can restrict the maximization over  $u(\theta)$  so that  $\theta u(\theta) - \hat{\lambda} c(u(\theta)) - m \geq \bar{k}/p(\theta)$ . Since  $(\theta u - \hat{\lambda} c(u))$  is strictly concave, with  $(\theta u - \hat{\lambda} c(u)) \rightarrow -\infty$  when either  $u \rightarrow \infty$  or  $u \rightarrow -\infty$ , this defines a closed, bounded interval for  $u(\theta)$ , for each  $\theta$ . Thus, there exists an  $M_{v,u} < \infty$  such that we can restrict the maximization to  $|u(\theta)| \leq M_{v,u}$ .

Hence, we can restrict the maximization in (24) to a compact set. Since the objective function is continuous over this restricted set, the maximum must be attained. ■

**Lemma 2** *The value function  $k(v)$  satisfies the Bellman equation (7)-(9).*

**Proof.** Suppose that for some  $v$

$$k(v) > \max_{u,w} \mathbb{E} [\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))]$$

where the maximization is subject to (22) and (23). Then there exists  $\Delta > 0$  such that

$$k(v) \geq \mathbb{E} [\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))] + \Delta$$

for all  $(u, w)$  that satisfy (22) and (23). But then by definition

$$k(w(\theta)) \geq \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t \tilde{u}_t(\theta^t) - \hat{\lambda} c(\tilde{u}_t(\theta^t))]$$

for all allocations  $\tilde{u}$  that yield  $w(\theta)$  and are incentive compatible. Substituting, we find that

$$k(v) \geq \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t) - \hat{\lambda} c(u_t(\theta^t))] + \Delta$$

for all incentive-compatible allocations that deliver  $v$ , a contradiction with the definition of  $k(v)$ . Namely, that there should be a plan with value arbitrarily close to  $k(v_0)$ . We conclude that  $k(v) \leq \max_{u,w} \mathbb{E} [\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))]$  subject to (22) and (23).

By definition, for every  $v$  and  $\varepsilon > 0$  there exists a plan  $\{\tilde{u}_t(\theta^t; v, \varepsilon)\}$  that is incentive compatible and delivers  $v$  with value

$$\sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t \tilde{u}_t(\theta^t; v, \varepsilon) - \hat{\lambda} c(\tilde{u}_t(\theta^t; v, \varepsilon))] \geq k(v) - \varepsilon.$$

Let  $(u^*(\theta), w^*(\theta)) \in \arg \max_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))]$ . Consider the plan  $u_0(\theta_0) = u^*(\theta_0)$  and  $u_t(\theta^t) = \tilde{u}_{t-1}((\theta_1, \dots, \theta_t); w^*(\theta_0), \varepsilon)$  for  $t \geq 1$ . Then

$$\begin{aligned} k(v) &\geq \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t) - \hat{\lambda} c(u_t(\theta^t))] \\ &= \mathbb{E}_{-1} \left[ \theta_0 u^*(\theta_0) - \hat{\lambda} c(u^*(\theta_0)) + \hat{\beta} \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_0 [\theta_{t+1} u_{t+1}(\theta^{t+1}) - \hat{\lambda} c(u_{t+1}(\theta^{t+1}))] \right] \\ &\geq \max_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))] - \hat{\beta} \varepsilon. \end{aligned}$$

Since  $\varepsilon > 0$  was arbitrary it follows that  $k(v) \geq \max_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))]$  subject to (22) and (23).

Finally, together both inequalities imply  $k(v) = \max_{u,w} \mathbb{E}[\theta u(\theta) - \hat{\lambda} c(u(\theta)) + \hat{\beta} k(w(\theta))]$  subject to (22) and (23). ■

## Proof of Theorem 2

**Part (a).** Suppose the allocation  $\{u_t\}$  is generated by the policy functions starting from  $v_0$ , is incentive compatible and delivers lifetime utility  $v_0$ . After repeated substitutions of the Bellman equation (7), we arrive at

$$k(v_0) = \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t) - \hat{\lambda} c(u_t(\theta^t))] + \hat{\beta}^T \mathbb{E}_{-1} k(v_T(\theta^T)). \quad (27)$$

Since  $k(v_0)$  is bounded above this implies that

$$k(v_0) \leq \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t) - \hat{\lambda} c(u_t(\theta^t))],$$

so  $\{u_t\}$  is optimal, by definition of  $k(v_0)$ .

Conversely, suppose an allocation  $\{u_t\}$  is optimal given  $v_0$ . Then, by definition it must be incentive compatible and deliver utility  $v_0$ . Define the continuation utility implicit in the allocation

$$w_0(\theta_0) \equiv \sum_{t=1}^{\infty} \beta^{t-1} \mathbb{E}_0 [\theta_t u_t(\theta^t)].$$

and suppose that either  $u_0(\theta) \neq g^u(\theta; v_0)$  or  $w_0(\theta) \neq g^w(\theta; v_0)$ , for some  $\theta \in \Theta$ . Since the original

plan  $\{u_t\}$  is incentive compatible,  $u_0(\theta)$  and  $w_0(\theta)$  satisfy (22) and (23). The Bellman equation then implies that

$$\begin{aligned} k(v_0) &= \mathbb{E}[g^u(\theta; v_0) - \hat{\lambda}c(g^u(\theta; v_0)) + \beta k(g^w(\theta; v_0))] \\ &> \mathbb{E}[u_0(\theta) - \hat{\lambda}c(u_0(\theta)) + \beta k(w_0(\theta))] \\ &\geq \mathbb{E}_{-1}[u_0(\theta_0) - \hat{\lambda}c(u_0(\theta_0))] + \sum_{t=1}^{\infty} \beta^t \mathbb{E}_{-1}[u_t(\theta^t) - \hat{\lambda}c(u_t(\theta^t))]. \end{aligned}$$

The first inequality follows since  $u_0$  does not maximize (7), while the second inequality follows the definition of  $k(w_0(\theta))$ . Thus, the allocation  $\{u_t\}$  cannot be optimal, a contradiction. A similar argument applies if the plan is not generated by the policy functions after some history  $\theta^t$  and  $t \geq 1$ . We conclude that an optimal allocation must be generated from the policy functions.

**Part (b).** First, suppose an allocation  $\{u_t, v_t\}$  generated by the policy functions  $(g^u, g^w)$  starting at  $v_0$  satisfies  $\lim_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) = 0$ . Then, after repeated substitutions of (8), we obtain

$$v = \sum_{t=0}^T \beta^t \mathbb{E}_{-1}[\theta_t u_t(\theta^t)] + \beta^T \mathbb{E}_{-1}[v_T(\theta^T)]. \quad (28)$$

Taking the limit we get  $v_0 = \sum_{t=0}^{\infty} \beta^t \mathbb{E}_{-1}[\theta_t u_t(\theta^t)]$  so that the allocation  $\{u_t\}$  delivers lifetime utility  $v_0$ . Next, we show that for any allocation generated by  $(g^u, g^w)$ , starting from finite  $v_0$ , we have  $\lim_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) = 0$ .

Suppose utility is unbounded above and  $\limsup_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) > 0$ . Then  $\hat{\beta} > \beta$  implies that  $\limsup_{t \rightarrow \infty} \hat{\beta}^t \mathbb{E}_{-1} v_t(\theta^t) = \infty$ . Since the value function  $k(v)$  is non-constant, concave and reaches an interior maximum, we can bound the value function so that  $k(v) \leq av + b$ , with  $a < 0$ . Thus,

$$\limsup_{t \rightarrow \infty} \hat{\beta}^t \mathbb{E}_{-1} k(v_t(\theta^t)) \leq a \limsup_{t \rightarrow \infty} \hat{\beta}^t \mathbb{E}_{-1} v_t(\theta^t) + b = -\infty$$

and then (27) implies that  $k(v_0) = -\infty$ , a contradiction since there are feasible plans that yield finite values. We conclude that  $\limsup_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) \leq 0$ .

Similarly, suppose utility is unbounded below and that  $\liminf_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) < 0$ . Then  $\liminf_{t \rightarrow \infty} \hat{\beta}^t \mathbb{E}_{-1} v_t(\theta^t) = -\infty$ . Using  $k(v) \leq av + b$ , with  $a > 0$ , we conclude that

$$\liminf_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} k(v_t(\theta^t)) = -\infty$$

implying  $k(v_0) = -\infty$ , a contradiction. Thus, we must have  $\liminf_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) \geq 0$ .

The two established inequalities imply  $\lim_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\theta^t) = 0$ .

**Part (c).** Suppose  $\limsup_{t \rightarrow \infty} \beta^t \mathbb{E}_{-1} v_t(\sigma^t(\theta^t)) \geq 0$  for every reporting strategy  $\sigma$ . Then after

repeated substitutions of (9),

$$v \geq \sum_{t=0}^T \beta^t \mathbb{E}_{-1} [\theta_t u_t(\sigma^t(\theta^t))] + \beta^T \mathbb{E}_{-1} v_T(\sigma^T(\theta^T)).$$

implying

$$v \geq \liminf_{T \rightarrow \infty} \sum_{t=0}^T \beta^t \mathbb{E}_{-1} [\theta_t u_t(\sigma^t(\theta^t))].$$

Therefore,  $\{u_t\}$  is incentive compatible, since  $v$  is attainable with truth telling from part (b).

## Proof of Lemma 1

**Part (a) (Strict Concavity)** Let  $\{u_t(\theta^t, v_0), v_t(\theta^t, v_0)\}$  be the plans generated from the policy functions starting at  $v_0$  (note: no claim of incentive compatibility is required). Take two initial utility values  $v_a$  and  $v_b$ , with  $v_a \neq v_b$ . Define the average utilities

$$\begin{aligned} u_t^\alpha(\theta^t) &\equiv \alpha u_t(\theta^t, v_a) + (1 - \alpha) u_t(\theta^t, v_b) \\ v_t^\alpha(\theta^t) &\equiv \alpha v_t(\theta^t; v_a) + (1 - \alpha) v_t(\theta^t; v_b) \end{aligned}$$

Theorem 2 part (b) implies that  $\{u_t(\theta^t, v_a)\}$  and  $\{u_t(\theta^t, v_b)\}$  deliver  $v_a$  and  $v_b$ , respectively. This immediately implies that  $\{u_t^\alpha(\theta^t)\}$  delivers initial utility  $v^\alpha \equiv \alpha v_a + (1 - \alpha) v_b$ . It also implies that there exists a finite time  $T$  such that

$$\sum_{t=0}^T \beta^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t, v_a)] \neq \sum_{t=0}^T \beta^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t, v_b)],$$

so that

$$u_t(\theta^t; v_a) \neq u_t(\theta^t; v_b), \quad (29)$$

for some history  $\theta^t \in \Theta^{t+1}$ . Consider iterating  $T$  times on the Bellman equations starting from  $v_a$  and  $v_b$ :

$$\begin{aligned} k(v_a) &= \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t; v_a) - c(u_t(\theta^t; v_a))] + \hat{\beta}^T \mathbb{E}_{-1} k(v_T(\theta^T; v_a)) \\ k(v_b) &= \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t(\theta^t; v_b) - c(u_t(\theta^t; v_b))] + \hat{\beta}^T \mathbb{E}_{-1} k(v_T(\theta^T; v_b)), \end{aligned}$$

and averaging we obtain

$$\begin{aligned}
\alpha k(v_a) + (1 - \alpha)k(v_b) &= \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t^\alpha(\theta^t) - [\alpha c(u_t(\theta^t; v_a)) + (1 - \alpha)c(u_t(\theta^t; v_b))]] \\
&\quad + \hat{\beta}^T \mathbb{E}_{-1} [\alpha k(v_T(\theta^T; v_a)) + (1 - \alpha)k(v_T(\theta^T; v_b))] \\
&< \sum_{t=0}^T \hat{\beta}^t \mathbb{E}_{-1} [\theta_t u_t^\alpha(\theta^t) - \alpha c(u_t^\alpha(\theta^t))] + \hat{\beta}^T \mathbb{E}_{-1} k(v_T^\alpha(\theta^T)) \\
&\leq k(v^\alpha),
\end{aligned}$$

where the strict inequality follows from the strict concavity of the cost function  $c(u)$ , the fact that we have the inequality (29), and the weak concavity of the value function  $k$ . The last weak inequality follows from iterating on the Bellman equation for  $v^\alpha$  since the average plan  $(u^\alpha, v^\alpha)$  satisfies the Bellman equations constraints at every step. This proves that the value function  $k(v)$  is strictly concave.

**(b) (Differentiability)** Since the value function  $k(v)$  is concave, it is sub-differentiable — that is, there is at least one sub-gradient at every point  $v$ . Differentiability can then be established by the following variational envelope arguments.

Suppose first that utility is unbounded below. Fix an interior value  $v_0$  for initial utility. For a neighborhood around  $v_0$  define the test function

$$W(v) \equiv \mathbb{E}[\theta(g^u(\theta, v_0) + (v - v_0)) - \hat{\lambda}c(g^u(\theta, v_0) + (v - v_0)) + \hat{\beta}k(g^w(\theta, v_0))].$$

Since  $W(v)$  is the value of a feasible allocation in the neighborhood of  $v_0$  it follows that  $W(v) \leq k(v)$ , with equality at  $v_0$ . Since  $W'(v_0)$  exists it follows, by application of the Benveniste-Scheinkman Theorem (see Theorem 4.10, in Stokey, Lucas and Prescott, 1989), that  $k'(v_0)$  also exists and

$$k'(v_0) = W'(v_0) = 1 - \hat{\lambda} \mathbb{E}[c'(u^*(\theta))]. \quad (30)$$

Finally, since  $c'(u) \geq 0$  this shows that  $k'(v) \leq 1$ .

Next, suppose utility is bounded below, say, by zero. Then the argument above establishes differentiability at a point  $v_0$  as long as  $g^u(\theta, v_0) > 0$ , for all  $\theta \in \Theta$ . However, corner solutions with  $g^u(\theta, v_0) = 0$  are possible here even with Inada assumption on the utility function, so a different envelope argument is required. We provide one that exploits the homogeneity of the constraint set.

If utility is bounded below, then  $\limsup_{t \rightarrow \infty} \mathbb{E}_{-1} \beta^t v_t(\sigma(\theta^t)) \geq 0$  for all reporting strategies  $\sigma$  so that, applying Theorem 2, a solution  $\{u_t\}$  to the planner's sequence problem is ensured. Then, for any interior  $v_0$ , the plan  $\{(v/v_0)u_t\}$  is incentive compatible and attains value  $v$  for the agent. In addition the test function

$$W(v) \equiv \sum_{t=0}^{\infty} \hat{\beta}^t \mathbb{E}_{-1} \left[ \theta_t \frac{v}{v_0} u_t(\theta^t) - \hat{\lambda} c \left( \frac{v}{v_0} u_t(\theta^t) \right) \right]$$

satisfies  $W(v) \leq k(v)$ ,  $W(v_0) = k(v_0)$  and is differentiable. It follows from the Benveniste-Scheinkman Theorem, that  $k'(v_0)$  exists and equals  $W'(v_0)$ .

The limit  $\lim_{v \rightarrow \bar{v}} k'(v) = -\infty$  follows immediately from  $\lim_{v \rightarrow \bar{v}} k(v) = -\infty$ , if  $\bar{v} < \infty$ . Otherwise it is inherited by the upper bound  $h(v, \beta)$  introduced in the proof of Theorem 1, since both  $\lim_{v \rightarrow \infty} h(v, \beta) = -\infty$  and  $\lim_{v \rightarrow \infty} \frac{\partial}{\partial v} h(v, \beta) = -\infty$ .

Finally, we show that  $\lim_{v \rightarrow \underline{v}} k'(v) = \infty$ . Consider the deterministic planning problem

$$\underline{k}(v) \equiv \max_u \sum_{t=0}^{\infty} \hat{\beta}^t (u_t - \hat{\lambda} c(u_t))$$

subject to  $v = \sum_{t=0}^{\infty} \beta^t u_t$ . Note that  $\underline{k}(v)$  is differentiable with  $\lim_{v \rightarrow \underline{v}} \underline{k}'(v) = \infty$ . Since deterministic plans are trivially incentive compatible, it follows that  $\underline{k}(v) \leq k(v)$ , with equality at  $\underline{v}$ . Then we must have  $\lim_{v \rightarrow \underline{v}} k'(v) = \infty$  to avoid a contradiction.

## Proof of Proposition 1

The CLAR equation was shown in the main text, so we focus here on the bounds. Consider the program

$$\max_{u,w} \sum_n \bar{p}_n \{ \bar{\theta}_n u_n - c(u_n) + \hat{\beta} k(w_n) \}$$

$$v = \sum_n \bar{p}_n (\bar{\theta}_n u_n + \beta w_n)$$

$$\theta_n u_n + \beta w_n \geq \theta_n u_{n+1} + \beta w_{n+1} \text{ for } n = 1, 2, \dots, K-1,$$

This problem and its notation require some discussion. We do not incorporate the monotonicity constraint on  $u$ . But this notation allows us to consider bunching in the following way. If any set of neighboring agents is bunched, then we group these agents under a single index and let  $\bar{p}_n$  be the total probability of this group. Likewise let  $\bar{\theta}_n$  represent the conditional average of  $\theta$  within this group, which is what is relevant for the promise-keeping constraint and the objective function. Let  $\theta_n$  be the taste shock of the highest agent in the group. The incentive constraint must rule the highest agent in each group from deviating and taking the allocation of the group above him.

Of course, every combination of bunched agents leads to a different program. We study all of them. The optimal allocation of our problem must solve one of these programs, although not necessarily the one that yields the highest value, since this one may not be feasible if the monotonicity condition is violated.

The first-order conditions are

$$\bar{p}_n \{ \bar{\theta}_n - \hat{\lambda} c'(u_n) - \lambda \bar{\theta}_n \} + \theta_n \mu_n - \theta_{n-1} \mu_{n-1} = 0$$

$$\bar{p}_n \{ \hat{\beta} k'(w_n) - \beta \lambda \} + \beta (\mu_n - \mu_{n-1}) = 0$$

where, by the Envelope theorem,  $\lambda = k'(v)$ . Summing the first-order conditions for consumption,

we get

$$\hat{\lambda} \mathbb{E}[c'(u(\theta))] = 1 - k'(v)$$

The first-order conditions for  $n = 1$  imply

$$(1 - \lambda) + \frac{\theta_1}{\bar{\theta}_1} \frac{\mu_1}{\bar{p}_1} = \frac{\hat{\lambda} c'(u_1)}{\bar{\theta}_1} \leq \frac{\hat{\lambda} \mathbb{E}[c'(u_\theta)]}{\bar{\theta}_1} = \frac{1 - \lambda}{\bar{\theta}_1}.$$

This implies

$$\frac{\mu_1}{\bar{p}_1} \leq \frac{1 - \lambda}{\bar{\theta}_1} - (1 - \lambda) \frac{\bar{\theta}_1}{\bar{\theta}_1}.$$

Using

$$k'(w_1) = \frac{\beta}{\hat{\beta}} \lambda - \frac{\beta}{\hat{\beta}} \frac{\mu_1}{\bar{p}_1},$$

we get

$$k'(w_1) \geq \frac{\beta}{\hat{\beta}} \left[ \lambda - \frac{1 - \lambda}{\bar{\theta}_1} + (1 - \lambda) \frac{\bar{\theta}_1}{\bar{\theta}_1} \right] = \frac{\beta}{\hat{\beta}} \left[ 1 + \frac{1}{\bar{\theta}_1} - \frac{\bar{\theta}_1}{\bar{\theta}_1} \right] k'(v) + \frac{\beta}{\hat{\beta}} \left[ \frac{\bar{\theta}_1}{\bar{\theta}_1} - \frac{1}{\bar{\theta}_1} \right].$$

Similarly, writing the first-order conditions for  $n = K$ , we get

$$(1 - \lambda) - \frac{\theta_{K-1}}{\bar{\theta}_K} \frac{\mu_{K-1}}{\bar{p}_K} = \frac{\hat{\lambda} c'(u_K)}{\bar{\theta}_K} \geq \frac{\hat{\lambda} \mathbb{E}[c'(u_\theta)]}{\bar{\theta}_K} = \frac{1 - \lambda}{\bar{\theta}_K}.$$

This implies

$$-\frac{\mu_{K-1}}{\bar{p}_K} \geq \frac{1 - \lambda}{\bar{\theta}_{K-1}} - (1 - \lambda) \frac{\bar{\theta}_K}{\bar{\theta}_{K-1}}.$$

Using

$$k'(w_K) = \frac{\beta}{\hat{\beta}} \lambda + \frac{\beta}{\hat{\beta}} \frac{\mu_{K-1}}{\bar{p}_K},$$

we get

$$k'(w_K) \leq \frac{\beta}{\hat{\beta}} \left[ \lambda - \frac{1 - \lambda}{\bar{\theta}_{K-1}} + (1 - \lambda) \frac{\bar{\theta}_K}{\bar{\theta}_{K-1}} \right] = \frac{\beta}{\hat{\beta}} \left[ 1 + \frac{1}{\bar{\theta}_{K-1}} - \frac{\bar{\theta}_K}{\bar{\theta}_{K-1}} \right] k'(v) + \frac{\beta}{\hat{\beta}} \left[ \frac{\bar{\theta}_K}{\bar{\theta}_{K-1}} - \frac{1}{\bar{\theta}_{K-1}} \right].$$

For any  $n$ ,  $w_K \leq w_n \leq w_1$ , we have for every  $n$

$$\begin{aligned} \frac{\beta}{\hat{\beta}} \left[ 1 + \frac{1}{\bar{\theta}_1} - \frac{\bar{\theta}_1}{\bar{\theta}_1} \right] k'(v) + \frac{\beta}{\hat{\beta}} \left[ \frac{\bar{\theta}_1}{\bar{\theta}_1} - \frac{1}{\bar{\theta}_1} \right] &\leq k'(w_n) \\ &\leq \frac{\beta}{\hat{\beta}} \left[ 1 + \frac{1}{\bar{\theta}_{K-1}} - \frac{\bar{\theta}_K}{\bar{\theta}_{K-1}} \right] k'(v) + \frac{\beta}{\hat{\beta}} \left[ \frac{\bar{\theta}_K}{\bar{\theta}_{K-1}} - \frac{1}{\bar{\theta}_{K-1}} \right]. \end{aligned}$$

After rearranging, we obtain

$$\begin{aligned} \frac{\beta}{\hat{\beta}} \left[ 1 + \frac{1}{\theta_1} - \frac{\bar{\theta}_1}{\theta_1} \right] (1 - k'(v)) + 1 - \frac{\beta}{\hat{\beta}} &\geq 1 - k'(g^w(\theta, v)) \\ &\geq \frac{\beta}{\hat{\beta}} \left[ 1 + \frac{1}{\theta_{K-1}} - \frac{\bar{\theta}_K}{\theta_{K-1}} \right] (1 - k'(v)) + 1 - \frac{\beta}{\hat{\beta}}. \end{aligned}$$

To arrive at the expression in the text we take the worst case scenario: we choose the subproblem that is most unfavorable to each bound, noting that  $1 - k'(v) \geq 0$ .

Turning to the bounded utility case, note that all the first-order conditions and constraints are satisfied when  $\lambda \geq 1$  with  $\mu_n = 0$  and  $u(\theta) = 0$  and  $w(\theta) = \beta^{-1}v > v$ . The first-order condition for  $w$  implies  $k'(w(\theta)) = k'(\beta^{-1}v) = (\hat{\beta}/\beta)k'(v)$ . Since the problem is strictly convex, this represents the unique solution.

Since establishing the lower bound involved no assumption on interior solutions for  $u$  this holds for all  $v$ . The upper bound, on the other hand, required  $u(\theta) > 0$  for all  $\theta$ , which must be true for high enough  $v$ , i.e. for low enough  $k'(v)$ .

## Proof of Proposition 2

Since the derivative  $k'(v)$  is continuous and strictly decreasing, we can define the transition function

$$Q(x, \theta) = k'(g^w((k')^{-1}(x), \theta))$$

for all  $x < 1$ . For any probability distribution  $\mu$ , let  $T_Q(\mu)$  be the probability distribution defined by

$$T_Q(\mu)(A) = \int 1_{\{Q(x, \theta) \in A\}} d\mu(x) dp(\theta)$$

for any Borel set  $A$ . Define

$$T_{Q,n} \equiv \frac{T_Q + T_Q^2 + \dots + T_Q^n}{n}$$

For example,  $T_{Q,n}(\delta_x)$  is the empirical average of  $k'(v_t)$  over all histories of length  $n$  starting with  $k'(v_0) = x$ .

**Lemma 4** *For each  $x < 1$  there exists a subsequence  $T_{Q,\phi(n)}(\delta_x)$  that converges weakly (i.e. in distribution) to an invariant distribution on  $(-\infty, 1)$  under  $Q$ .*

**Proof.** The bounds (11) derived in Proposition 1 imply that

$$\lim_{x \downarrow 1} Q(x, \theta) = \lim_{v \rightarrow -\infty} k'(g^w(\theta, v)) = \beta/\hat{\beta} < 1.$$

We first extend the continuous transition function  $Q(x, \theta) : (-\infty, 1) \times \Theta \rightarrow (-\infty, 1)$  to a continuous transition function  $\hat{Q}(x, \theta) : [-\infty, 1] \times \Theta \rightarrow (-\infty, 1)$ , with  $\hat{Q}(1, \theta) = \beta/\hat{\beta}$  and  $\hat{Q}(x, \theta) = Q(x, \theta)$ ,

for all  $x \in (-\infty, 1)$ . It follows that  $T_{\hat{Q}}$  maps probability distributions over  $[-\infty, 1]$  to probability distributions over  $(-\infty, 1)$ , and  $T_Q(\delta_x) = T_{\hat{Q}}(\delta_x)$ , for all  $x \in (-\infty, 1)$ .

We next show that the sequence  $\{T_{\hat{Q},n}(\delta_x)\}$  is tight, in that for any  $\varepsilon > 0$  there exists a compact set  $A_\varepsilon$  such that  $T_{\hat{Q},n}(\delta_x)(A_\varepsilon) \geq 1 - \varepsilon$ , for all  $n$ . The expected value of the distribution  $T_{\hat{Q}}^n(\delta_x)$  is simply  $\mathbb{E}_{-1}[k'(v_t(\theta^{t-1}))]$  with  $x = k'(v_0) < 1$ . Recall that  $\mathbb{E}_{-1}[k'(v_t(\theta^{t-1}))] = k'(v_0)(\beta/\hat{\beta})^t \rightarrow 0$ . This implies that

$$\begin{aligned}\min\{0, k'(v_0)\} &\leq \mathbb{E}_{-1}[k'(v_t(\theta^{t-1}))] \\ &\leq T_{\hat{Q}}^n(\delta_x)(-\infty, -A)(-A) + (1 - T_{\hat{Q}}^n(\delta_x)(-\infty, -A))1\end{aligned}$$

for all  $A > 0$ . Rearranging,

$$T_{\hat{Q}}^n(\delta_x)(-\infty, -A) \leq \frac{1 - \min\{0, x\}}{A + 1}$$

which implies that  $\{T_{\hat{Q}}^n(\delta_x)\}$ , and therefore  $\{T_{Q,n}(\delta_x)\}$ , is tight.

Tightness implies that there exists a subsequence  $T_{\hat{Q},\phi(n)}(\delta_x)$  that converges weakly (i.e. in distribution) to some  $\pi$ . Since  $\hat{Q}(x, \theta)$  is continuous in  $x$ , then  $T_{\hat{Q}}(T_{\hat{Q},\phi(n)}(\delta_x))$  converges weakly to  $T_{\hat{Q}}(\pi)$ . But the linearity of  $T_{\hat{Q}}$  implies that

$$T_{\hat{Q}}(T_{\hat{Q},\phi(n)}(\delta_x)) = \frac{T_{\hat{Q}}^{\phi(n)+1}(\delta_x) - T_{\hat{Q}}(\delta_x)}{\phi(n)} + T_{\hat{Q},\phi(n)}(\delta_x)$$

and since  $\phi(n) \rightarrow \infty$  we must have  $T_{\hat{Q}}(\pi) = \pi$ .

Recall that  $T_{\hat{Q}}$  maps probability distributions over  $[-\infty, 1]$  to probability distributions over  $(-\infty, 1)$ . This implies that  $\pi = T_{\hat{Q}}(\pi)$  has no probability mass at  $\{1\}$ . Since  $T_Q$  and  $T_{\hat{Q}}$  coincide for such distribution it follows that  $\pi = T_Q(\pi)$ , so that  $\pi$  is an invariant distribution on  $(-\infty, 1)$  under  $Q$ .

When utility is bounded below and either utility is bounded above or  $\hat{\gamma} < 1$  then there exists an upper bound on the ergodic set for  $v$ . This in turn implies lower bound  $v_L > 0$  for the ergodic set defined as the minimum of the policy function  $g^w$  over the set of values of  $v$  with  $k'(v) \leq 1$ , since  $g^w$  is never zero and continuous on a compact set it attains a positive minimum. The argument then follows along similar lines as above. ■
